But then if there is a certain movement in accord with nature, there could not be only forced spatial movement or forced rest. So if the earth now remains at rest by force, it also came together at the center by being carried [toward it] because of the vortex; for everyone says that this is the cause, on the basis of what happens in liquids or in the case of air; for, in these, greater or heavier things are always carried toward the center of the vortex. That is why, then, everyone who says that the heaven came to be says that the earth came together at the center; and they seek the cause of why it remains at rest there. And some, speaking in this way, say that its flatness and magnitude is the cause, while others, like Empedocles,[106] say that it is the spatial movement of the heaven which, rotating in a circle and spatially moving faster than the earth, prevents [the earth from moving], just like the water in ladles; for when in fact a [bronze] ladle spatially moves in a circle the water is often below the [rim of the] bronze [ladle] but nonetheless does not spatially move downward, though it is natural for it to spatially move so, due to the same cause. And yet if neither the vortex nor the flatness is doing the preventing, and instead the air [below] gives way,[107] where will the earth move to? For it moved to the center by force, and remains at rest by force. But it is necessary for it to have, at any rate, some spatial movement in accord with nature. Is this, then, upward, downward, or where? For it is necessary for it to have some sort of movement. But if it is no more downward than upward, and the air above does not prevent it spatially moving upward, nor would the air below prevent the earth from doing so downward; for it is necessary for the same things to be a cause of the same things for the same things.

Further, against Empedocles, one might also say the following. For when the elements had been disaggregated separately by the strife, what cause was there of the earth's immobility? For of course he will not make the vortex the cause also at that time. But it is indeed absurd not to reflect on the following question: previously the parts of the earth spatially moved toward the center because of the vortex; but what is the cause due to which all things that have heaviness now move toward the earth? For the vortex is not near us.

295b1 Further, due to what cause does fire spatially move upward? For it is not because of the vortex. But if it naturally moves somewhere, it is clear that one must suppose that the earth does too.

105. 1.2, but also 276a22–26.
106. B35 DK.
107. Reading ὑπελθόντος.

Moreover, heavy and light are certainly not determined by the vortex either; instead, heavy and light things exist prior [to the vortex], one lot going to the center, the other lot rising to the surface because of the movement. Therefore, the one lot were heavy and the other light before the vortex came to be, but by what are they determined? And what spatial movement is natural for them? And to where? For if the unlimited exists, it is impossible for there to be an up or down, and the heavy and light are determined by these.

Most people, then, spend their time on these causes. But there are some who say that the earth remains at rest because of the similarity, as among the ancient thinkers Anaximander does;[108] for it is no more fitting for what is situated at the center and stands in a similar relation to the extremes to spatially move upward than downward or to the side; and it is impossible for it to make a movement in contrary directions at the same time. So of necessity it remains at rest.

This, though stated in a subtle way, is not stated in a true one; for according to this argument, it is necessary for anything placed at the center to remain at rest, so that fire too will rest there; for what was mentioned is not a special affection of earth. But this is not necessary. For it is not only evident that it remains at rest at the center, but also that it spatially moves toward the center. For where any part of it spatially moves to, there is where it is necessary for the whole of it to spatially move to as well; and where it spatially moves to in accord with nature, there is where it also remains at rest in accord with nature. Therefore, it does not [remain at rest] because of standing in a similar relation to the extremes (for this is common to all), while spatially moving toward the center is a special affection of earth.

It is also absurd to inquire why earth remains at rest at the center, but not to inquire why fire does so at the extremity. For if the extremity is by nature its place, it is clear that it is necessary for there also to be some place for earth by nature. But if this place [at the center] is not its by nature, but instead it remains at rest because of the necessity of the similarity (as in the argument about the hair that, when stretched strongly but similarly in every direction, will not break; or the one about the person who is very hungry and very thirsty, but equally so, and at an equal distance from food and drink; for he too [so the argument goes] is necessarily at rest), they must inquire about fire's immobility at the extremes.

Also a cause of wonder is their inquiring about the immobility but not inquiring about the spatial movement of these things, that is, due to what cause one spatially moves upward and the other toward the center, when nothing hinders them.

Moreover, what they do say is not even true. To be sure it is coincidentally true, in the sense that it is necessary for anything to remain at rest at the center for which it is no more fitting to move here than there. But on this argument at least [the earth] will not remain at rest, not—to be sure—as a whole, but having been dispersed. For the same argument will also apply to fire; for once placed there it must remain at rest

108. A11, A26 DK.

in the same way as earth; for it will stand in a similar relation to any point of the extremities. But nonetheless it will spatially move away from the center (as it appears to do) toward the extremity, if something does not prevent it; except, not as a whole toward one point (for it is only on the basis of the argument from similarity that it is necessary for this to happen), but rather a proportional part to a proportional part of the extremity—I mean, for example, a quarter of it toward a quarter of the encompassing [extremity] (for no body is a point). And just as what is condensed can come together from a larger to a smaller place, so what becomes rarer can do so from a smaller to a larger one. So the earth would also move in this way away from the center, even on the argument from similarity, if this were not by nature the place of earth.

These, then, are pretty much all the suppositions about the shape of the earth, as well as about its place, immobility, and movement.

2.14
The Earth (2)

On our own behalf, let us first say whether the earth has a movement or remains at rest; for, as we said,[109] some people make it one of the stars, while others put it at the center and say that it winds—that is, moves—around the central pole. That this is impossible is clear if one takes as a starting-point that, if indeed it spatially moves, whether it is outside the center or at the center, it is necessary for it to be moved with this movement by force; for the movement does not belong to the earth itself; for then each of its parts would also have this spatial movement. But as things stand they all spatially move in a straight line toward the center. That is why [the proposed winding movement of it], being forced and contrary to nature, cannot be eternal. The order of the cosmos, however, is eternal.

Further, all spatially moving bodies that spatially move in a circle appear to be left behind and to move with more than one spatial movement, in addition to the **296b1** primary one, so that it would be necessary for the earth as well, whether it spatially moves around the center or while situated at the center, to move with two spatial movements. But if this happens, it is necessary for there to be a passing and turning of the fixed stars.[110] It is evident, however, that this does not occur, but that instead the same stars always rise and set at the same places on the earth.

Further, the spatial movement in accord with nature of the parts of earth and of the whole earth is toward the center of the universe; for it is because of this, indeed, that as things stand the earth is situated at the center. But since the center of both [the earth and the universe] is the same, one might raise this puzzle: toward which center do things having heaviness, in particular, the parts of the earth, spatially move

109. 293a17–b32.

110. The planets (including the sun and the moon) undergo a movement along the ecliptic as well as a sidereal movement along with the fixed stars.

in accord with nature—is it because it is the center of the universe, or because it is the center of the earth? It is necessary, surely, that it be toward that of the universe; for light bodies, in particular, fire, in spatially moving in the contrary direction to heavy ones, spatially move toward the extremity of the place that encompasses the center. It happens, however, that the center of the earth is the same as that of the universe; for heavy bodies also spatially move toward the center of the earth, albeit coincidentally, insofar as it has its center at the center of the universe. A sign that they also spatially move toward the center of the earth is that things having heaviness spatially moving toward it move not in parallel but at similar angles, so that they spatially move toward one center, which is also that of the earth.[111]

It is evident, therefore, that it is necessary for the earth to be at the center and immovable, both due to the causes mentioned and because things having heaviness that are thrown straight upward by force spatially move back again perpendicularly to the same point, even if the capacity involved throws them an unlimited distance.

That the earth, then, neither moves nor is situated outside the center is evident from these considerations. In addition, the cause of the earth's immobility is clear from what has been said. For if it is naturally such as to spatially move by nature from anywhere toward the center, as is evident it is, and fire in turn from the center to the extremity, it is impossible for any part of it to spatially move from the center unless it is forced; for one [body] has one spatial movement; a simple one has a simple one, not contrary ones; and one from the center is contrary to one toward the center. If, therefore, it is impossible for any part whatever to spatially move from the center, it is evident that it is yet more impossible for the whole to do so; for where the part is naturally such as to move to, is also where the whole is naturally such as to do so. So, if indeed it is impossible for it to move except because of a greater strength, it is necessary for it to remain at rest at the center.

Also bearing witness to these things is what is said by the mathematicians about astronomy; for the things that appear to be so, the interchange of the configurations by which the order of the stars is determined, presuppose that the earth is situated at the center.

About the place of the earth, then, and the manner of its immobility and movement, let this much be said.

As for its shape, it is necessary that it have a spherical shape; for each of its parts has heaviness up to the point at which [it is] near to the center, and when a smaller part is pushed by a greater one it cannot swell to form a wave, but rather the first is squeezed together by the second and combines with it, until it arrives at the center. One should understand what is being said as if the earth comes to be in the way in which some of the natural scientists say it came to be. Except that they give the force

111. Eratosthenes of Cyrene (297–195 BC) discovered this empirically by observing that the sun shone directly down a well at high noon on the day of the summer solstice in one place and cast a shadow on the side of another at a distant place directly south of the first. So it is at least possible that Aristotle knew it in the same way.

as the cause of the downward spatial movement. It is better, however, to set out what is true and say that this happens because what has heaviness is of a nature to spatially move toward the center. When the mixture, then, was [merely] potential, the things that were disaggregated spatially moved from every direction toward the center in a similar way. Whether, then, the parts were similarly divided at the extremes from which they were brought together toward the center, or were in another state, it will produce the same result. It is evident, then, that when bodies spatially move in a similar way from all directions toward a single center, the mass must become similar in every direction; for when an equal quantity is added in every direction, it is necessary for the extremity to be at an equal distance from the center; and this is the shape of a sphere. And it will make no difference to the argument even if its parts did not travel together in a similar way from all directions toward the center. For it is necessary for a greater part always to push forward a smaller one that is in front of it up to the center, when both have balance-weight, and for a heavier one to push a less heavy one forward up to this.

Indeed, the following puzzle that someone might raise has the same resolution as these [difficulties]: Since the earth is at the center and is spherical, if a heavy thing many times as heavy were added to one hemisphere, the center of the universe and of the earth will not be the same. So either the earth will not remain at rest at the center, or if indeed it does remain at rest, it will rest even without occupying the center, which is where it naturally moves to as things stand.

297b1 This, then, is what is puzzling. But it is not difficult to see [through] once we have tightened things up a little and determined the way in which we think of a body of any magnitude whatever as moving toward the center, when it has heaviness. For it is clear that it does not do so up to the point at which its extremity makes contact with the center. Instead, the greater body must exert mastery until it occupies the center with its center; for it retains its balance-weight up to this point.

There is no difference, therefore, between saying this of a clod, or of any random part, or of the whole of the earth; for the result was stated not because of smallness or magnitude, but with reference to everything that has balance-weight up to the center.

So whether it spatially moved from somewhere as a whole or in parts, it is necessary for it to move up to the point until it occupies the center in a similar way in every direction, the smaller parts being counterbalanced by the larger ones by the forward push of its balance-weight.

If, then, the earth has come to be, it is necessary for it to have come to be in this way, so that it is evident that its coming to be was spherical, and, if it has not come to be but persists forever, remaining at rest, it is necessary for it to be in precisely the same way as the way it would first have come to be in, if it had come to be.

According to this argument, then, it is necessary for the earth's shape to be spherical, and because all things having heaviness spatially move at similar angles and not in parallel, and this is natural for [what spatially moves] toward what is by nature spherical. Either the earth is spherical, then, or it is by nature, at any rate, spherical.

One must, however, speak of each thing as being the sort of thing it tends to be, and the sort it in fact is,[112] by nature, and not the sort it is by force and contrary to nature.

Further, [it is necessary for the earth's shape to be spherical] also because of what seems to be so according to perception; for otherwise lunar eclipses would not have sections of the sort they do; for, as things stand, in its monthly configurations the moon takes on all sorts of divisions (for it becomes straight, gibbous, and crescent), but during eclipses it always has a convex defining line, so that if indeed it is eclipsed because of the interposition of the earth, the circumference of the earth, being spherical, would be the cause of the [line's] shape.

Further, because of the appearance of the stars, not only is it evident that the earth is round, but also that its magnitude is not great; for when we change our position a little to the south or to the north the circle of the horizon clearly becomes visibly other than it was, so that the stars overhead change greatly, and the same ones do not appear to those who move to the north as to the south; for some stars are seen in Egypt and around Cyprus but are not seen in the regions to the north, and those stars always apparent in regions to the north set in the former regions. So not only is it clear from these things that the shape of the earth is round, but also that it is of a sphere that is not great in size; for otherwise it would not make [the changes of the horizon] so quickly visible when we have changed our position by so little.

That is why those who suppose that the place around the Pillars of Heracles is connected to that around India, and in such a way that there is one sea, do not seem to suppose anything too unconvincing: they say, using elephants as their proof, that their kind is found in both extreme places, on the supposition that it is because of the connection between these extreme places that they share this feature with each other.

Also, the mathematicians[113] who try to calculate the size of the earth's circumference say that it is about four hundred thousand stades. On the basis of these proofs, it is necessary not only for the mass of the earth to be spherical, but also for it not to be great in relation to the magnitude of the other stars.

BOOK 3

3.1
Summary of Previous Books and of Previous Views on Coming to Be

We have previously discussed the primary heaven and its parts, further, the stars spatially moving within it, of what they are composed and of what sort their nature is, and in addition [proved] that they are incapable of coming to be and incapable of passing away.

112. Reading ὃ ὑπάρχει.
113. Perhaps Archytas or Eudoxus.

Since of the things we say are by nature, some are substances, others works and affections of these—by "substances" I mean the simple bodies (for example, fire and earth and those co-ordinate with these), and whatever is composed of them (for example, the whole heaven and its parts), and, again, both animals and plants and their parts; by "affections" and "works," I mean the movements of these and of other [substances], that is, of whichever movements these, in accord with the capacity within them, are the cause; further, to their alterations and their transformations into each other)—it is evident that the investigation of nature is mostly concerned with bodies; for all natural substances are either bodies or come to be along with bodies and magnitudes. This is clear from the definition of what sorts of things are by nature and from the theoretical investigation of each of them.

We have now spoken about the first of the elements, about what sort its nature is, and [proved] that it is incapable of passing away and incapable of coming to be.[114] It remains to speak about the other two.[115] But at the same time it will turn out that speaking about them also involves having investigated coming to be and passing away; for either coming to be does not exist at all or exists only in these elements and the things composed of them. But perhaps this is what we must first get a theoretical grasp on: whether it exists or not.

Those prior [to us] who philosophized about the truth, however, have disagreed both with the accounts at present being stated by ourselves and with each other.

For some of them did away with coming to be and passing away altogether (for none of the beings, they say, either comes to be or passes away, but it only seems to us so)—for example, the followers of Melissus and Parmenides.[116] Of them, we must hold that, even if they speak correctly about other things, they do not do so in a way appropriate to natural science at least; for the existence of certain beings that are incapable of coming to be and are wholly immovable is rather a matter for an investigation that is distinct from and prior to the natural scientific one.[117] But because these thinkers assumed that there is no other sort beyond the substance of perceptible beings, and were the first to understand that there had to be certain natures of this [unchangeable] sort if indeed there was going to be any knowledge or wisdom, they transferred to perceptible beings the accounts applicable to those natures.[118]

Others, as if on purpose, had the contrary belief. For some—especially the followers of Hesiod, and next, of the others, the first people who spoke about nature—say that none of the things at issue is incapable of coming to be, but that all come to be, although some, having come to be, remain incapable of passing away, while others pass away again.

---

114. I.e., primary body (284a30) or ether (270b22).
115. I.e., earth and fire, between which water and air are intermediate.
116. Aristotle discusses their views in *Ph.* 1.2.
117. I.e., primary philosophy (*Met.* 6.1).
118. This suggests that the followers of Parmenides and Melissus referred to include Platonists (*Met.* 1040b27–34, 1086a37–b6).

Others say that all things come to be and flow, none of them being stable, save one thing only that persists, from whose natural changing of shape all these things come. This is precisely what Heraclitus of Ephesus, among many others, seems to wish to say.

And there are also some who make all bodies capable of coming to be, putting them together from and dissolving them into planes.[119]

About the others there will be an account on another occasion.[120] But as for those who speak in this last way, that is, who compose all bodies from planes, it is a superficial matter to see that the other things they say are in conflict with mathematics.[121] And yet it is just either not to alter mathematics or to alter it [only] by means of arguments that are more convincing than its hypotheses. It is clear, then, that on the same account on which a solid is composed of planes, a plane is composed of lines, and these of points. But if so, it is not necessary for a part of a line to be a line. These are matters we have previously investigated in the discussions concerning movement,[122] [proving] that there are no indivisible lengths.

But as regards natural bodies, we should on this occasion too get a theoretical grasp on the impossible things that those who produce indivisible lines result in saying; for although the resulting impossibilities will follow for natural things as well, not all the ones that apply to the latter will apply to the others, because the others, the mathematical ones, are said of things on the basis of abstraction,[123] while the natural ones are said of things on the basis of an additional posit.[124]

There are many affections that cannot belong to indivisible things but necessarily belong to natural ones. For example, if there is an indivisible one;[125] for in an indivisible thing it is impossible for there to be something divisible, but all affections are divisible in two ways; for they are so either in form or coincidentally: in form, for example, of color, white, and black; coincidentally, if what it belongs to is divisible, so that the simple affections are all divisible in this way. That is why one must investigate the impossibility in the case of this latter sort.

If it is impossible, then, when each of the two parts has no weight at all, for the two together to have weight, while the perceptible bodies, either all or some, have weight (for example, earth and water), as our opponents themselves would admit, and a point has no weight at all, it is clear that neither do lines, and it they do not, then neither do planes, and so none of the bodies do either.

But then that a point cannot have weight is evident. For everything heavy can be heavier than something else, and everything light lighter—though perhaps what is

119. E.g., Plato, *Timaeus* 53a–57d.
120. There is some further discussion in 3.5, as well as in *Ph.* and *Met.*
121. The reference is probably to the Platonic rejection of geometrical points.
122. *Ph.* 5, 6, and 8.
123. *Met.* $1061^{a}28$–35.
124. I.e., perceptible matter (*Met.* 6.1).
125. Reading οἷον εἴ τί ἐστιν ἀδιαίρετον.

299ᵇ1 heavier or lighter is not necessarily heavy or light. Just as the great is greater [than something else], though what is greater is not always great; for there are many things that are unconditionally small, but nonetheless are larger than other things. If, then, something that, because it is heavy, would be heavier than something else, is necessarily greater by weight than it, everything heavy would be divisible. But a point was assumed to be indivisible.

Further, if what is heavy is something dense, and what is light something rare, and dense differs from rare in containing a greater quantity in an equal mass, then, if a point is heavy or light, it is also dense or rare. But what is dense is divisible, while a point is indivisible.

And if it is necessary for everything heavy to be either soft or hard, it is easy to infer an impossibility from this. For a soft thing is what can be pressed into itself, while a hard one is what cannot be pressed in. But what can be pressed in is divisible.

Moreover, no weight can result from things that do not have weight. For in the case of how many[126] will this in fact result and in what way? And how, without wishing to fabricate something, will they determine this? Also, if every weight greater than a weight is greater by a weight, it will follow that each of the parts that has no parts[127] will have weight; for if four points have weight, what is composed of a greater number of points has a weight greater than the weight of that body. And if it is necessary for a weight that is greater than a weight to be so by a weight, just as what is more white than something white is so by [a degree of] white, so that, when the weight equal [to four points] has been subtracted, the greater will be of greater weight by one point, and the result will be that the one point will also have weight.[128]

Further, if the planes can only be put together side-to-side along a line, it is absurd; for just as there are two ways [we might think] to put lines together, along the length [that is, end to end] and along the width [that is, one on top of the other], a plane should be the same way in regard to another plane. But a [Platonic] line is capable of being put together with a line by being put on top of it and not by being added to it [at its ends]. But then if indeed it is also possible [for planes] to be put together by being put one on top of the other, there will be some body that is neither an element nor composed of elements, consisting of planes put together in this way.

Further, if bodies are heavier due to the number of their planes, as is declared in
300ᵃ1 the *Timaeus*,[129] it is clear that the line and the point will also have weight; for they stand in a proportional relation to each other, as we also said previously.[130] If, on the other hand, they do not differ in this way but due to earth's being heavy and fire light,

126. Reading καὶ πῶς.
127. Reading ἕκαστον τῶν ἀμερῶν.
128. Reading ὥστε τὸ μεῖζον μιᾷ στιγμῇ βαρύτερον ἔσται ἀφαιρεθέντος τοῦ ἴσου, ὥστε καὶ ἡ μία στιγμὴ βάρος ἕξει.
129. 56b.
130. 299ᵇ18–23.

some planes will be heavy and others light. And what is more, their lines and points will be the same way; for the plane of earth will be heavier than the one of fire.

In general, the result is that either there is no magnitude at all, or magnitude can be done away with, if indeed as point stands in relation to line, line stands to plane, and it to body; for if all of them can be resolved into each other, they will be resolved into the primary ones, so that it is possible for points alone to exist, but no body.

Besides this, if time stands similarly, it would be done away with at a certain moment or could possibly be done away with; for the indivisible now is like a point on a line.

The same result follows for those who compose the heaven from numbers; for there are some thinkers, such as certain Pythagoreans, who compose nature from numbers;[131] for it is evident that natural bodies have heaviness and lightness, while units can neither produce bodies by being put together nor have weight.

3.2
Every Simple Body Has a Natural Movement; How Non-natural Movement Occurs

That it is necessary for some movement to belong by nature to all simple bodies is clear from the following. For since it is evident that they move, it is necessary that they be moved by force, if they do not have a movement proper to them. But "by force" and "contrary to nature" are the same thing. But then if there is some movement [of them] contrary to nature, it is necessary for there also to be one in accord with nature, to which it is contrary. And if the movements contrary to nature are many, the movement in accord with nature is one; for each of them moves in accord with nature in a simple way, while contrary to nature each has many movements.

Further, this is also clear from rest; for rest too is necessarily either by force or in accord with nature. And a thing remains at rest by force where it spatially moves to by force, and remains at rest in accord with nature where it spatially moves to in accord with nature. Since, then, it is evident that something remains at rest at the center, if it does so in accord with nature, it is clear that its spatial movement thereto is also in accord with nature for it, while if it remains at rest there by force, what prevents it from spatially moving? If it is something at rest, we will recycle the same argument; for it is necessary that either it is in accord with nature that the first resting thing is at rest or it will go on without limit, which is precisely what is impossible. On the other hand, if something moving is what prevents it from spatially moving, as Empedocles says that the earth rests because of the vortex, where could the earth spatially move to, since to go on without limit is impossible?[132] For nothing impossible happens, and **$300^{b}1$**

131. *Met.* $1083^{b}8$–19.
132. $295^{a}7$–$^{b}9$.

to traverse what is without limit is impossible. So it is necessary for what spatially moves to stop somewhere, and there it remains at rest, not by force but in accord with nature. But if there is rest in accord with nature, there is also movement in accord with nature, namely, the spatial movement to this place [of rest in accord with nature].

That is why Leucippus and Democritus, who say that the primary bodies are always moving in the void and unlimited, must say what sort of movement it is and what movement of theirs is in accord with nature. For if the elements are moved by each other by force, still it is necessary for each also to have a movement in accord with nature, to which the forced one is contrary. Also the primary mover must move not by force but in accord with nature; for it will go on without limit, if there is not some primary mover that moves in accord with nature, but always a prior one that moves because it is moved by force.

The same difficulty necessarily results if, as is written in the *Timaeus*,[133] before the cosmos comes to be, the elements moved in a disorderly way. For it is necessary for movement to be either forced or in accord with nature. But if they were moved in accord with nature, it is necessary for there to be a cosmos—if one wishes to get a scientific theoretical grasp on the issue; for it is necessary for the primary mover to move itself, moving in accord with nature, and for the ones that are moving not by force and remain at rest in their proper places to produce the very order they have as things stand, the ones having heaviness [moving] toward the center, and the ones having lightness away from the center. And this is the order that the cosmos has.

Further, one might ask whether it is not possible for some of the things moving in a disorderly way to be so mixed together as to be the ones from which bodies composed in accord with nature are composed (I mean, for example, bones and flesh), as Empedocles says happens under the reign of love; for he says: "Many heads sprouted without necks."[134]

As for those who posit unlimitedly many things moving in unlimited [spatial movements], if their mover is one, it is necessary for them to be spatially moving with one spatial movement, with the result that they will not be moving in a disorderly way. On the other hand, if their movers are unlimitedly many, it is necessary for
301ᵃ1 the spatial movements to be many as well; for if they are limitedly many, there will be some sort of order; for it is not by their spatially moving to the same place that disorder results; for nor is the case, as things stand, that all things spatially move to the same place, but only those of the same kind.

Further, what is disorderly is nothing other than what is contrary to nature; for the proper order of perceptible things is nature. In any case, this very thing is absurd and impossible, that what is unlimited has a disorderly movement; for the nature of things is that which most of them have and for most of the time. The result, then,

133. 30a, 52d–53b.
134. B57 DK.

for these thinkers is the contrary, that disorder is in accord with nature, while order and the cosmos are contrary to nature; and yet nothing in accord with nature comes about by luck. It seems, though, that Anaxagoras grasped at least this correctly; for he starts his cosmogony from unmoving things. Others too try [elements that] are aggregating somehow and again moving and disaggregating. But to produce the coming to be [of the cosmos] from things divided up and moving is not reasonable. That is why Empedocles omits it from what happens under the reign of love; for he could not compose the heaven, establishing it from things separated but made to aggregate because of love; for the cosmos is composed of elements that are disaggregated, so that it is necessary for it to have come to be from a single aggregated thing.

That there is a natural movement for each of the [simple] bodies, with which it is moved neither by force nor contrary to nature, is evident from these considerations.

On the other hand, that it is necessary for there to be some that have a balance-weight of heaviness and lightness is clear from the following. For we say[135] that it is necessary for them to move. But if the moved thing will not have by nature a balance-weight, it is impossible for it to move either toward the center or away from the center.

For let A be without heaviness, and B have heaviness, and let the one without heaviness spatially move a distance CD, and let B in an equal time spatially move a distance CE (for the one that has heaviness will move a greater distance). If, then, the body that has heaviness is divided in the ratio CE to CD (for it is possible that this is the relation it stands in to one of its parts), if the whole spatially moves the whole of CE, the part must spatially move CD in an equal time. So what has no heaviness will spatially move the same distance as what has heaviness—which is precisely what is impossible. The same argument also applies to lightness.

Further, if there is to be some moving body that has neither lightness nor heaviness, it is necessary for it to be moved by force, and, if it is moving by force, it will make an unlimited movement. For since what moves a body is a capacity, and a smaller and lighter body will be moved further by the same capacity, let A, the one without heaviness, be moved a distance CE, and B, the one with heaviness, be moved CD in an equal time. If, then, the body having weight is divided in the ratio CE to CD, the result will be that the part subtracted from the body having heaviness is moved CE in equal time, since the whole was moved CD. For as the greater body is to the smaller, so will the speed of the smaller be to the speed of the greater. Therefore, a body without weight and one having weight will spatially move an equal distance in the same time. But this is impossible. So, since the body without heaviness will be moved a distance greater than any given distance, it would spatially move an unlimited one. It is evident, then, that it is necessary that every definite body have heaviness or lightness.

135. 300^{a}20–21.

Since nature is a starting-point of movement within the thing itself, a capacity is a starting-point of movement within another thing, or within the thing itself insofar as it is other, and all movement is either in accord with nature or by force, the one in accord with nature (for example, that of a stone downward), will be made faster by what is in accord with a capacity, while the one contrary to nature will be wholly due to this capacity. In either case, air is used like an instrument (for air is naturally both light and heavy). Insofar as it is light, it produces spatial movement upward, when it is pushed and gets a starting-point [of movement] from a capacity, and again downward insofar as it is heavy; for, in either case, the capacity transmits it by, as it were, attaching [it to the air]. That is why what is moved by force continues to spatially move without the mover following along with it. For without a body of this sort there would be no movement by force. And it assists the movement in accord with nature of each thing in the same way.

That all [definite bodies] are either light or heavy, then, and how movements contrary to nature take place in them, is evident from these considerations.

That there is neither coming to be of everything nor of simply nothing, is clear from what was said previously;[136] for it is impossible for there to be a coming to be of every body, unless it is also possible for there to be a void that is separated; for the place in which what is now coming to be will be, if it were to come to be, in this place it is necessary for there to be a void previously, since no body existed in it. For it is possible for one body to come to be from another (for example, fire from air), but, in general, for it to do so from no preexisting other magnitude is impossible. What is potentially a certain sort of body may certainly become such actively. But if the potential body is not actively some other body previously, there will be a void that is separated.

3.3
The Nature of an Element

It remains to say of what sorts of bodies there is coming to be and why. Since, then, in all cases knowledge is through the things that are primary, and primary among the constituents are the elements, we must investigate what sorts of the bodies in question are the elements, and why, and next after that what their number is and what their qualities are.

This will be evident once we have set down what the nature of an element is. Let, then, an element of bodies be what the other bodies are divided into, present in them either potentially or actively (for which of the two ways is still a matter for dispute), and is not itself divisible into things distinct in form; for something like this is what everybody in any context wishes to mean by "element."

136. 298ᵇ14–24.

If, then, what was stated is an element, it is necessary for there to be some bodies of this sort. For fire and earth are present potentially in flesh and wood and each thing of this sort; for it is evident that the former are segregated out of the latter. But neither flesh nor wood is present in fire either potentially or actively; for otherwise it would be segregated out. Similarly, even if there were only one thing of this sort, even then it would not be present in it; for if there is going to be flesh, bone, or any of the others whatever, we must not at all say that they are potentially present [in the element], but rather we must get a further theoretical grasp on what their mode of coming to be is.

Anaxagoras says things contrary to Empedocles about the elements. For Empedocles says that fire, earth, and the ones co-ordinate to these are elements of bodies and that everything is composed of these, while Anaxagoras says the contrary; for he says that the uniform things are the elements (I mean flesh, bone, and each of the others of that sort), and that air and fire are mixtures of these and of the other "seeds";[137] for each is composed of a mixum-gatherum of all invisible uniform things. That is why everything comes to be from these; for he calls fire and ether the same thing.

But since every natural body has a proper movement, and some movements are simple, others mixed, and mixed ones are of mixed bodies, and simple ones of simple bodies, it is evident that there will be certain bodies that are simple. For there are also simple movements. So it is clear that there are elements and why.

3.4
The Number of Elements; Atomism Refuted

The next thing to investigate would be whether there are a limited number of them or an unlimited, and if a limited one, how many they are.

First, then, we must theoretically grasp that there are not, as some people think, an unlimited number. And we will begin with those who make all the uniform things elements, as Anaxagoras also does. For none of those who think in this way correctly conceives of an element; for we see many mixed bodies that are divisible into uniform parts—I mean, for example, flesh, bone, wood, and stone. So if indeed what is composite is not an element, not every uniform thing will be an element, but rather one that cannot be divided into things distinct in form, as was said previously.[138]

Further, even if an element is conceived of in this way, it is not necessary to make an unlimited number; for one will achieve the same results if one takes them to be limited in number; for one will produce the same result, even if there are only two or three such things, as Empedocles tries to prove. For since even on their view not everything is produced from uniform things (for they do not produce faces from

137. B2–4 DK.
138. $302^{a}18$.

faces, nor any other of the things that in accord with nature have a certain shape), it is evident that it is much better to make the starting-points limited in number, indeed as few as possible, consistent, at any rate, with all the same things being proved to follow, just as the mathematicians also demand; for they always take starting-points that are limited in form or in number.

Further, if body is said to be distinct from body in accord with their proper differences, and the differences of bodies are limited in number (for they are differentiated by their perceptual qualities, and these are limited in number; but this must be proved), it is evident that it is necessary for the elements to be limited in number as well.

But then what other people—for example, Leucippus and Democritus of Abdera[139]—say does not have reasonable consequences either; for they say that the primary things are unlimited in number but indivisible in magnitude, and that neither do many things come to be from one nor one from many, but rather that it is by the interweaving—that is, the combination—of the primary ones that all things will come to be. For in a certain way these thinkers too make all the beings be numbers and composed of numbers; for even if they do not make it perspicuously clear, nonetheless this is what they wish to say.

Also, in addition to these considerations, since bodies differ in shape, and the shapes are unlimited in number, they say that the simple bodies are unlimited in number as well. But of what sort and what the shape of each of the elements is, they have not further determined at all, except they have assigned the spherical shape to fire.[140] On the other hand, air, water, and the others they determine by greatness and smallness, regarding their nature as a sort of a universal seedbed for all the elements.

First of all, then, Leucippus and Democritus make the same error of not taking a limited number of starting-points, though it is possible to state the same results from them.

Further, if the differences of the shapes are not unlimited in number, it is clear that the elements will not be unlimited in number.

In addition to these considerations, it is necessary to be in conflict with the mathematical sciences in speaking of indivisible bodies and to do away with many acceptable beliefs and things that appear to be so to perception, which have been spoken about previously in the [accounts] concerning time and movement.[141]

At the same time, though, it is even necessary for them to contradict themselves; for it is impossible, if the elements are indivisible, for greatness and smallness to differentiate air, earth, and water; for then they cannot come to be from each other; for the greatest bodies will always come to an end in being segregated out—which is the way they say water, air, and earth come to be from each other.

139. F194.
140. *DA* 403b28–404a16.
141. Especially *Ph.* 6.1–2.

Further, not even according to their supposition should one believe that the elements come to be unlimited in number, if indeed the [simple] bodies are differentiated by their shapes, and all shapes are composed of pyramids, rectilinear ones of rectilinear ones, and the sphere of its eight parts. For it is necessary that there be certain starting-points of the shapes. So whether they are one, two, or many, the simple bodies will be the same in number too.

Further, if for each of the elements there is a proper movement, and that of a simple body is simple, and the simple movements are not unlimited in number (because the simple spatial movements are not more than two and the places are not unlimited in number), the elements would not be unlimited in number either.

3.5
There Is More Than One Element

But since it is necessary for the elements to be limited in number, it remains to investigate whether there is more than one. For certain people suppose that there is only one, and some suppose that it is water, others air, others fire, and others something finer-grained than water and denser than air, which, being unlimited, they say encompasses all the heavens.

Those who make this one element water, air, or something more fine-grained than water but denser than air, and have other things come to be from these by rarefaction and condensation, all fail to notice that they themselves are making [an element] something that is prior to the element in question; for coming to be from their elements is composition, they say, and the one back into the elements, dissolution, so that it is necessary for the finer-grained one to be prior in nature. Since, then, they say that of all the bodies fire is the most fine-grained, fire would be primary in nature. But [whether it is fire or not] makes no difference, for it is necessary that a certain one among the other bodies be primary, and not the intermediate one.

Further, having the other things generated by condensation and rarefaction is no different from having them be so by fine-grainedness and density; for they wish the fine-grained to be rare, and the coarse-grained to be condensed. But, in turn, fine-grainedness and coarse-grainedness is the same as largeness and smallness; for what has small parts is fine-grained and what has large parts is coarse-grained; for what spreads itself out widely is fine-grained, and what is composed of small parts is like that. So for these thinkers the result is that it is by greatness and smallness that they distinguish the substance of the other [bodies]. But for those distinguishing things in this way the result will be to say that all things are relatives, and that fire, water, and air will not unconditionally be, but rather the same thing will be fire relative to one thing, but air relative to another. This is precisely what results too for those who say that there are several elements, saying that they differ [only] in greatness and smallness; for since each is defined by its quantity, their magnitudes will

be in a certain ratio to each other, so that it is necessary for the things that have this ratio to each other to be air, fire, earth, or water, because of the ratio between smaller magnitudes present in greater ones.

Those, on the other hand, who suppose fire to be the element avoid this [difficulty] indeed, but for them other unreasonable consequences necessarily result.

For some of them fasten a shape to fire, like those who make it pyramidal, and of these, the more simple-minded ones say that it is because the shape most capable of piercing is the pyramid, and the body most capable of doing so is fire; but the ones more subtle in argument put forward in addition that all bodies are composed of the most fine-grained one and the solid figures of pyramids, so that, since fire is the most fine-grained of the bodies, and the pyramid has the smallest parts and is primary, and the primary figure belongs to the primary body, fire would be pyramidal.

Others prove nothing by reasoning about the shape, but only make this body the finest-grained one, and say that from it in composition the others come to be, as if they were growing together specks of dust.

For both lots, however, the same difficulties result; for if they make the primary body indivisible, the arguments stated previously will come back again against this hypothesis.

Further, it is not open to those who wish to get a theoretical grasp on things in a way appropriate to natural science to say this. For if every body is comparable to another body with respect to quantity, and the magnitudes of the uniform ones stand in the same proportional relation to each other as their elements do (for example, as the magnitude of the totality of water is to that of the totality of air, so that of the element of the one is to that of the element of the other), and if there is more air than water, and, in general, more of a fine-grained one than of a coarse-grained one, it is evident that the element of water will also be smaller than that of air. If, then, the smaller magnitude is contained in the greater one, the element of air would be
304b1 divisible. And similarly for fire and, in general, for what is more fine-grained.

If, however, the primary body is divisible, then the result for those who assign a shape to fire is that a part of fire is not fire, because a pyramid is not composed of pyramids, and further, that not every body will be either an element or composed of elements (for a part of fire will be neither fire nor any other element). For those who differentiate by magnitude, on the other hand, the result is an element prior to their element, and this goes on without limit, if indeed every body is divisible, and the one with the smallest parts is their element.

Further, for these too the result is one of saying that the same thing is fire in relation to one thing, air in relation to another, and, again, water and earth.

An error common to all who suppose a single element is to produce one natural movement only, the same for everything. For we see that every natural body has a starting-point of movement. If, then, all the bodies are one thing, the movement of all of them would be one. And with this one it is necessary for them, by just as much as they become bigger, to move more, just as fire by as much as it becomes bigger,

spatially moves faster with the upward spatial movement that is its own. But the fact is that many things spatially move downward faster [the bigger they become].

So, because of these considerations, and in addition to them, seeing that it has been determined previously that there are several natural movements, it is clear that it is impossible for the element to be a single one. And since there is neither an unlimited number nor just one, it is necessary for there to be several and limited in number.

3.6
Elements Are Not Eternal but Come to Be from Each Other

First, though, we must investigate whether the elements are eternal or are coming to be and passing away; for when this is proved it will also be evident both how many and of what sort they are.

But for them to be eternal is impossible; for we see fire, water, and each of the simple bodies dissolving. And it is necessary for their dissolution either to be unlimited or for it to come to a stop. If it is unlimited, the time of their dissolution will also be unlimited, and, again, that of their composition; for each part is dissolved and constituted in a distinct time. So the result will be that outside the one unlimited time there is another unlimited one, when that of composition is unlimited and, a further one, that of the dissolution prior to it [was unlimited too]. So outside the unlimited time an unlimited one comes to be—which is precisely what is impossible. **305^{a}1**

On the other hand, if the dissolution will come to a stop somewhere, the body at which it stops will be either indivisible or, as Empedocles seems to wish to say, divisible though in fact never divided.

But indivisible it will not be, because of the arguments stated previously.[142] But then neither is it divisible though in fact never divided. For a smaller body is more easily destroyed than a larger one. If indeed, then, a larger one is destroyed by this process of destruction, so that it is dissolved into smaller ones, it is reasonable that a smaller one will be yet more affected by it. But we see fire being destroyed in two ways; for it is destroyed by being extinguished by its contrary, and also by itself, when it dies away. And the smaller is affected in this way by the larger, and the faster the smaller it is. So it is necessary for the elements of bodies to be capable of passing away and coming to be.

But since they are capable of coming to be, their coming to be will be either from an incorporeal thing or from a body, and, if from a body, either from another body or from each other.

The account saying that the elements are generated from an incorporeal thing produces a separated void. For everything that comes to be does so in something and that something in which the coming to be takes place will be either something

142. 299^{a}2–11, 303^{a}20–24.

incorporeal or something that has a body. And if it is one that has a body, there will be two bodies in the same place, the one that comes to be and also the preexisting one.[143] On the other hand, if it is incorporeal, it is necessary for there to be a definite void. But that this is impossible was proved previously.[144]

But then neither can the elements come to be from some body. For the result will be that there is another body prior to the elements. But if this one has heaviness or lightness, it will be one of the elements; and if it has no balance-weight it will be immovable and mathematical, and, being such, will not be in a place. For the place it is at rest in is the place it is also capable of moving in. And if by force, contrary to nature, and if not by force, in accord with nature. If, then, it is in a place, that is, somewhere, it will be one of the elements; while, if it is not in a place, nothing will be composed of it; for it is necessary for what comes to be and what it comes to be from to be together.

Since the elements cannot come to be either from an incorporeal thing or from another body, it remains for them to come to be from each other.

3.7
How Elements Come to Be from Each Other; the Views of Empedocles and Plato Refuted

Next in turn, then, we must investigate what the way is in which they come to be from each other, whether as Empedocles and Democritus say, as those who dissolve them into planes do, or in some other way beyond these.

305b1 Those who follow Empedocles and Democritus are unaware that they do not produce coming to be of one thing from another, but only apparent coming to be; for they say that each one is present and is segregated out, as if coming to be were from a vessel, and not from certain matter, and did not involve change.

Next, even if things were this way, the results would be no less unreasonable. For the same quantity does not seem to become heavier when compressed. But it is necessary for them to say this, if they claim that water is present in air and is segregated out of it; for water, when it comes to be from air, is heavier [than the air].

Further, in the case of mixed bodies, it is not necessary, when one of the two components is segregated out, for it always to occupy a bigger place. However, when air comes to be from water, it does take up a bigger place; for the finest-grained one comes to be in a bigger place. This is evident too, indeed, in a case of transformation; for when a liquid becomes vaporized or pneumaticized[145] the vessels encompassing the liquid masses break apart due to the lack of space [within them]. So if, in general,

143. *Ph.* 213b20.
144. 301b33–302a9.
145. *Juv.* 479b31–32, *GA* 755a14–21, 762a18–21.

there is not a void and bodies cannot expand, as those who say these things claim, the impossibility [of this phenomenon] is evident. On the other hand, if there is a void and expansion, it is unreasonable that of necessity what is segregated out always takes up a bigger place.

It is also necessary for the coming to be from each other to come to a stop, if indeed in a limited quantity there is not present an unlimited number of limited quantities. For when water comes to be from earth, a quantity is subtracted from the earth, if indeed coming to be is by segregating out. And, in turn, when one is subtracted from the remainder, it is the same way. If, then, this will go on forever, in what is limited what is unlimited will be present. Since this is impossible, the generation of the elements from each other could not go on forever. That their change into each other, then, is not by segregating out, has been recounted.

It remains that they come to be by changing into each other. And this in two ways; for it is either by change of shape, as from the same wax either a sphere or a cube can come to be, or by dissolution into planes, as some people say.

If, then, it comes about by change of shape, saying that the [simple] bodies are indivisible follows by necessity; for if they are divisible, a part of fire will not be fire, nor a part of earth earth, because a part of a pyramid is not in every case a pyramid, nor a part of a cube a cube.

On the other hand, if it comes about by the dissolution into planes, first, it is absurd that not all the elements are generated from each other, which is precisely what it is necessary for these people to say, and what they do say. For it is neither reasonable for one thing alone to be exempt from transformation, nor does it appear to be in accord with perception, but rather all alike appear to transform into each other. The result is that people speaking about the things that appear to be so say things that are not in agreement with the things that appear to be so. And the cause of this is not correctly grasping the primary starting-points, but instead wishing to lead everything back to certain previously determined beliefs. For presumably the starting-points of perceptible things must be perceptible, of eternal ones, eternal, of things capable of passing away, things capable of passing away, and, in general, each must be of the same kind as what falls under it. But out of love for these beliefs of theirs they seem to do the same thing as those defending their theses in [dialectical] arguments; for they submit to every consequence on the supposition that they possess true starting-points, as if starting-points must not sometimes be judged on the basis of what follows from them, and most of all on the basis of the end. And the end in the case of productive science is the work, and in that of natural science what appears to be so to perception has the controlling vote in every case.

The result for these thinkers is that earth is most of all an element, and it alone is incapable of passing away, if indeed the incapable of dissolving is incapable of passing away and is an element; for earth alone is incapable of dissolving into another body.

Moreover, in the case of those that do dissolve, the dangling of the triangles is not reasonable either.[146] But this happens whenever one thing is transformed into another, because of the numerical inequality of the triangles that compose them.

Further, it is necessary for those who state these views to make coming to be not be from a body; for when something comes to be from planes, it will not come to be from a body.

In addition to these things, it is necessary for them to say that not all body is divisible, yet this will conflict with the most exact sciences; for these, the mathematical ones, suppose even an intelligible [body] to be divisible, while these thinkers, because of their wish to save their hypothesis, do not even admit that all perceptible [body] is divisible. For it is necessary for those who produce a shape for each of the elements and define their substance by it to make these elements indivisible; for a pyramid or a sphere divided in a certain way will not leave a remainder that is a sphere or a pyramid. So either a part of fire will not be fire—but rather there will be something prior to that element, because everything is either an element or composed of elements—or else not every body will be divisible.

3.8
Elements Are Not Differentiated by Their Shape

In general, the attempt to assign a shape to the simple bodies is unreasonable, first, because the result will be that the whole will not be filled up; for among plane figures three shapes seem to fill the [whole of] place, triangle, square, and hexagon, and among the solids two only, pyramid and cube. But it is necessary to suppose more of these because they posit more [than two] elements.

Next, it is evident that all the simple bodies take their shape from the encompassing place, especially water and air. It is impossible, then, for the shape of the element to remain constant; for, if it did, the whole [thing] would not be on every side in contact with what encompasses it. But then if its shape will be changed, it will no longer be water, if indeed it was differentiated by [its] shape. So it is evident that there are no definite shapes for these elements.

Indeed, it seems that nature itself indicates to us what is in accord with reason; for just as in other cases the underlying subject must be formless and shapeless (for in this condition it would be most capable of receiving shape, like the all-receptive written about in the *Timaeus*[147]), in the same way too the elements must be considered as matter for the composite bodies. That is why indeed, being separate from their qualitative differences, they are capable of changing into each other.

146. When something composed of n + m triangles is dissolved into something composed of m triangles, n triangles will be left dangling, not composing any body at all. This is unreasonable because non-bodies cannot occupy space or drift around in it.
147. 50b–c.

In addition to these considerations, how is it possible for flesh, bone, or any other of the continuous bodies whatever to come to be? For they cannot do so from the elements themselves, because what is continuous does not come to be from what is composite, nor from the composition of planes; for it is elements that would come to be by composition and not the bodies composed of elements. So if one wishes to argue in an exact way and not accept views of this on the basis of a passing glance at the arguments, one will see that they do away with the coming to be of the beings.

Moreover, the shapes attributed to bodies are discordant with the very affections, capacities, and movements they especially looked toward in assigning the shapes as they do. For example, since fire is most capable of movement, and also is capable of heating and of burning, some people made it a sphere, others a pyramid; for these are the most capable of movement because they have minimal contact and are the least stable, and are also most capable of heating and most capable of burning, because the one is wholly angle, and the other has the sharpest angles, and it is by their angles, they say, that they burn and heat. **307^{a}1**

In the first place, with reference to movement both lots are in error; for even if these shapes are the most capable of movement, yet they are not most capable of the movement of fire; for that of fire is upward and rectilinear, while these shapes are most capable of moving in a circle—so-called rolling. Next, if earth is a cube because it is stable and remains at rest, but it remains at rest not in any random place but in its own place, and spatially moves away from anywhere else unless prevented, and fire and the others are the same way, it is clear that fire too and each of the elements will be a sphere or pyramid in an alien place, but in its proper one will be a cube.

Further, if fire heats and burns because of its angles, all the elements will be capable of heating, though one perhaps more than another; for all have angles—for example, the octahedron and the dodecahedron. (For Democritus indeed even the sphere, since it is a sort of angle, cuts because it is most capable of movement.[148]) So the elements will differ [only] in the more and less.[149] But it is evident that this is false.

At the same time it will result that even mathematical bodies heat and burn; for they too have angles and include indivisible spheres and pyramids (anyhow if, as these thinkers say, there are in fact indivisible magnitudes). For if one lot [of shapes] do and another lot do not [heat and burn], they must state the difference, and not state it simply in the way they do state it.

Further, if what is burned becomes fire, and fire is a sphere or pyramid, it is necessary for what is burned to come to be spheres or pyramids. Grant, as in accord with reason, that cutting and dividing are a result of these shapes. But that a pyramid of necessity produces pyramids or a sphere spheres is entirely non-rational, and is as if someone were to think a knife divides things into knives or a saw into saws.

148. When you bend a straight line it forms a sort of (blunt or curved-tip) angle. Thus a sphere is a solid (curved) angle.
149. *HA* 486^{a}14–^{b}22.

Further, it is ridiculous to assign the shape to fire only with a view to dividing; for fire seems more to aggregate and bring together than to disaggregate. For it disaggregates things of different kinds, but aggregates those of the same kind. And while
307b1 the aggregating is intrinsic to it (for bringing together and uniting are characteristic of fire), the disaggregating is coincidental (for it is in aggregating what is of the same kind that it removes what is alien). So either they should have looked toward both when they assigned [it a shape] or, better, toward the aggregating.

In addition to these considerations, since hot and cold are contraries in capacity, it is impossible to assign any shape to cold; for the shape assigned to it must be contrary to [the one assigned to hot], but no shape is contrary to a shape. That is why all these thinkers omit this.[150] And yet it was fitting to have defined all by shape or none. Some, though, in having tried to say something about this capacity contradicted themselves. For what has large particles, they say, is cold, because it compresses and cannot pass through the ducts.[151] It is clear, therefore, that what is hot would be what does pass through. But something of that sort always has small particles. So the result is that hot and cold are differentiated by their largeness and smallness, and not by their shapes. Further, if the pyramids are unequal in size, the large ones would not be fire and neither would their shape be a cause of burning, but rather the contrary.

It is evident, then, from these considerations that the elements are not differentiated by their shapes. And since the most fundamental differences of bodies are their affections, works, and capacities (for we say that each of the things that are by nature has works, affections, and capacities), we must speak about these first, in such a way that having got a theoretical grasp on them we would get hold of the differences between one another.

BOOK 4

4.1
Heavy and Light

Concerning heavy and light, what each of them is and what their nature is must be investigated, and due to what cause they have these capacities of theirs. For a theoretical investigation concerning these is proper to accounts dealing with movement; for we say that things are heavy or light in virtue of their being capable of being moved naturally in a certain way. (To the activations of these, though, names are not assigned, unless it was thought that "balance-weight" is such.)

150. I.e., assigning a shape to cold.
151. Plato, *Timaeus* 62a–b.

Because the study of natural science concerns movement, and these things have within them some spark, as it were, of movement, all thinkers make use of their capacities, but—except for a few—have not defined them. **308ª1**

Having first looked at what other people have said, then, and gone through the puzzles that it is necessary for this investigation to go through, let us then state the things that appear to us to be so about these matters.

Heavy and light, then, are said of things unconditionally and in relation to something else; for of things having heaviness, we say that one is lighter, the other heavier—for example, bronze is heavier than wood. About the ones said unconditionally nothing has been said by our predecessors, though about those in relation to something else they did speak; for they do not say what heavy is and what light is, but only what heavier or lighter is in things that have heaviness. This will be clearer if we state it as follows. For some things always and naturally move spatially away from the center, while others do so toward the center. Among these, the ones that spatially move away from the center move upward, I say, the ones toward the center downward.

For it is absurd not to think that there is up and down in the heaven, as some people claim; for there is no up and down, they say, if indeed the heaven is similar in every direction, and from whatever point a given person traverses it, he will come to his own antipodes.[152] For our part, we say that the extremity of the universe is up, both up as regards position and as being by nature primary. And since the heaven has an extremity and a center, it is clear that there will be an up and a down, as even ordinary people say, except not on adequate grounds. The cause of this inadequacy is that they think that the heaven is not similar in every direction, but that the hemisphere above us is the only one, since if they supposed in addition that it was like this all around, with the center similarly related to all of it, they would say that the extremity is up, the center down.

We say, then, that the unconditionally light is what spatially moves upward, that is, toward the extremity, and the unconditionally heavy is what spatially moves downward, that is, toward the center. By contrast, we say that one thing is light or lighter in relation to something else, when of two bodies having heaviness and being equal in mass, the other by nature spatially moves downward faster.

4.2
Examination of Previous Views

Among those of our predecessors, then, who set out to investigate these things, pretty much the majority have spoken only about what is heavy and light in this relative way, in which of two things having heaviness, one is lighter than the other. And

152. Plato, *Timaeus* 62b–63e.

having proceeded in this way they think they have also made determinations about
308ᵇ1 what is unconditionally heavy or light. But their argument does not apply to these. This will become clearer as we advance.

For some of them speak of lighter and heavier in the way one finds it written about
5 in the *Timaeus*,[153] where the heavier is what is composed of the greater number of the same sort of parts, the lighter what is composed of fewer, as in the case of lead a greater quantity of lead is heavier, and in the case of bronze a greater quantity of bronze. And likewise for each of the other bodies that are the same in form; for to be heavier lies in the superior number of equally [heavy] parts. And in the same way,
10 they say, lead is heavier than wood; for all bodies are composed of the same things and of one matter, though they do not seem to be.

Having made determinations in this way, then, they have said nothing about what is unconditionally light or heavy; for as things stand fire is always light and spatially moves upward, while earth and all earthen things spatially move downward, that is, toward the center, so that it is not because of the small number of the triangles
15 of which, they say, each [body] is composed, that fire naturally moves upward; for otherwise a greater quantity would have spatially moved less and been heavier, being composed of a greater number of triangles. But as things stand it is evident that the contrary happens; for the greater the quantity of fire, the lighter it is and the faster it spatially moves upward. And from up to down a smaller quantity of fire will spatially
20 move faster, and a larger one more slowly.

In addition to these considerations, since to be lighter is to have fewer of the homogeneous parts and to be heavier is to have more, and air, water, and fire are composed of the same triangles, though differing in being less numerous and more numerous, due to which some of these are lighter and others heavier, there
25 will be some quantity of air that will be heavier than water. But entirely the contrary happens; for the larger the quantity of air the more it always spatially moves upward, and any part of air whatever spatially moves upward out of water.

This, then, is the way some people have made determinations about light and heavy. Others, however, did not believe it sufficient to determine them in this way,
30 but rather, even though they are of an older generation, they had a more novel understanding of the things now being discussed. For it is evident that certain bodies, though their mass is smaller, are heavier than others. It is clear, then, that is not sufficient to say that bodies composed of an equal number of primary things are equal in weight; for then they would be equal in mass. While for those who say that planes are
35 the primary and indivisible things of which bodies having heaviness are composed,
309ª1 it is absurd to say this; for those who say that they are solids it is more open to say that the greater of them is the heavier. As for composites, since it is evident indeed that not each of them has [heaviness] in this way, but we see many heavier ones to be smaller in mass (for example, bronze in comparison to wool), some people think up

153. 63c–e.

and state another cause; for the void enclosed in the bodies lightens them, they say, sometimes making the larger ones lighter; for they have more void. For it is because of this too that the greater mass is often composed of the same number of solid particles [as the lesser] or even of fewer. And in general, in fact, in every case the cause of being lighter is enclosing more void.

They speak, then, in this way. But it is necessary for those who make their determinations in that way to add that the body not only contains more void, but also less of what is solid; for if the proportion of solid will exceed that of void, it will not be lighter. For it is because of this too, they say, that fire is lightest, because it contains more void. The result will be, then, that a large quantity of gold containing more void will be lighter than a small quantity of fire, unless it also contains many times as much solid. So this must be said [in addition].

Among those denying the existence of a void, some have determined nothing about light and heavy—for example, Anaxagoras and Empedocles. Others, however, having made determinations, while denying the existence of a void, said nothing about why there are bodies that are unconditionally light or heavy, that is, why the one lot spatially moves always upward and the other lot downward. And they made no mention either about there being some bodies that are greater in mass but lighter than smaller bodies, nor is it clear, on the basis of what has been said, how what they say will be in agreement with the things that seem to be so.

On the other hand, it is necessary for those who explain the lightness of fire by taking the cause to be its containing a larger quantity of void to be subject to pretty much the same difficulties. For while it will contain less solid and more void than other bodies, nonetheless there will be some quantity of fire in which the solid and full part exceeds the solid ones encompassed in some small quantity of earth. If they were to say that there is also an excess of void, how will they determine what is unconditionally heavy? Surely, either by its containing more solid or by its containing less void. If, then, this is what they will say, there will be some quantity of earth so small that in it there will be less solid than **309**^{b}**1** in a large quantity of fire. Similarly, if they determine this by using the void, there will be a body lighter than what is unconditionally light and always spatially moves upward, while this body is always spatially moving downward. But this is impossible; for the unconditionally light is always lighter than what has heaviness and moves downward, while what is lighter is not always light, because, among the things that have heaviness, one is said to be lighter than another—for example, water than earth.

Moreover, neither will having void stand in a proportional relation to plenum be sufficient to resolve the puzzle now under discussion. For speaking in this way will result in the same impossibility. For in a larger and a smaller quantity of fire the solid will have the same ratio to the void. But the larger quantity of fire spatially moves upward faster than the smaller one, and, conversely, in the same way a larger quantity of gold or of lead spatially moves downward faster than a smaller one. Similarly, for each of the other things that have heaviness. But this should not be the case, if indeed heavy and light are determined by this [sort of proportional relation].

It is also absurd if it is because of the void that some things spatially move upward, but the void itself does not move. But then if void naturally moves spatially upward, and plenum downward, and this is why they are respectively the cause of these spatial movements in other things, there is no need to investigate why some composite bodies are light and others heavy, but rather to say about void and plenum themselves why one is light and the other has heaviness, and further, due to what cause plenum and void do not stand apart from each other.

It is also unreasonable to make a place for the void, as if the void is not itself a sort of place. But it is necessary, if indeed the void is to move, for there to be some place belonging to it, a place from which its change [starts] and a place to which it [is directed].

In addition to these considerations, what is the cause of movement? For it is surely not the void; for it is not void alone that is moved, but solid as well.

The results are the same if one were to determine things in another way, by having smallness and largeness make one thing heavier or lighter than another, or establishing them in some other way, whatever it might be, but only assigning the same matter to all, or if more than one, a pair of contraries only.

For if there is one matter, as there is for those who compose things from triangles, there will not be unconditional heaviness or lightness. On the other hand, if there are contrary ones, as there are for those with void and plenum, there will not be for the things intermediate between the unconditionally heavy and unconditionally light ones a cause due to which one is heavier or lighter than another or than the unconditional ones.

To determine these by largeness and smallness seems more like a fabrication than the previous ones; but because it can produce differences between each of the four elements, it is better safeguarded against the foregoing puzzles. But making things have one nature, though differing in size, necessarily has the same result as for those who make them have one matter, that nothing is unconditionally light or spatially moves upward, except by being passed by other things or being squeezed out, and that many small things are heavier than a few large ones. If this is going to be the case, however, the result will be that a large quantity of air or a large quantity of water will be heavier than a small quantity of water or earth. But this is impossible.

These, then, are the things said by others, and this the way they are stated.

4.3
The Movement of Heavy and Light Bodies

Speaking for ourselves, though, our first task is one of making determinations about something that certain thinkers are most puzzled by, namely, why it is that, in accord with nature, some bodies always spatially move upward, others downward, and others

both upward and downward, and, after this, about heaviness and lightness and the coincidental affections pertaining to them, and due to what cause each comes about.

About the spatial movement of each thing toward its own place, we must make the same supposition as about the other sorts of coming to be and of change. For there are three sorts of movement (with respect to size, with respect to form, and with respect to place), and in each of these we see the change coming about from contraries to contraries or to intermediates, and not a change from what is random to what is random. Similarly, neither is a random thing capable of moving a random thing. Instead, just as what is capable of being altered and capable of being increased are distinct, so too are what is capable of altering and what is capable of increasing. In the same way, then, we must suppose about both what is capable of moving and of being moved with respect to place that a random thing is not capable of moving or being moved by a random thing.

If, then, what is capable of moving upward or downward is what is capable of making heavy or capable of making light, and what is moved is what is potentially heavy or light, the spatial movement of each body toward its own place is spatial movement toward its own form.

(This is more how one should take what the ancients said, that like spatially moves to like. For this does not result in every case; for if one were to displace the earth to where the moon is now, each of its parts would spatially move not toward the earth, but to just where it in fact is now. In general, however, when bodies that are similar and undifferentiated are moved with the same movement, this must result, that the place toward which it is natural for any one part to spatially move toward is also the place it is natural for all of it to move toward. But since place is the limit of what encompasses, and the extremity and the center encompass all the things moving upward and downward, and they become, in a way, the form of what is encompassed, it is to its like that a body moves when it moves to its own place; for the successive ones are like each other—for example, water is like air and air is like fire. And it is possible to reverse the intermediate ones, but not the extremes—for example, air is like water, water is like earth; for the relation of each higher body to the one falling below it is always that of form to matter, and this is how they relate to each other.[154]) **$310^{b}1$**

To investigate, then,[155] why fire spatially moves upward and earth downward, is the same as investigating why what is capable of being made healthy, when moved and changed insofar as it is capable of being made healthy, proceeds toward being healthy and not toward whiteness. Likewise too for all the other things capable of alteration. But also whatever is capable of being increased, when it changes insofar as it is capable of increase, proceeds not toward being healthy but toward an increased

154. When up is associated with form and down with matter ($312^{a}15–16$), earth emerges as least formed (and so closer to matter), water more formed than earth (and so closer to fire and the upward place), air yet more formed, and fire most formed.
155. Reading δὴ.

size. And it is likewise too in the case of each of them, one changes in quality, another in quantity, and, in place, light ones [proceed] upward, heavy ones downward.

The one exception is that these seem to have a starting-point of change within themselves (I mean the heavy and the light), while the others do not, but rather an external one—for example, what is capable of being made healthy and what is capable of being increased. And yet sometimes these too change of themselves, and on a small movement coming about in what is external, the one proceeds toward health, the other toward increase. And since the same thing that is capable of being made healthy is receptive of disease, if it is moved insofar as it is capable of being made healthy, it moves toward health, if it is moved insofar as it is [capable of being made] diseased, toward disease.

But the heavy and light, more than these, appear to have within themselves the starting-point, because their matter is closer to their substance. A sign of this is that spatial movement belongs to independent things, and in coming to be is the last of the movements, so that this movement would be primary with respect to substance. When, then, air comes to be from water and light from heavy, it progresses upward. And at the same time it is light, and is no longer becoming so, but in that place it is so. It is evident, then, that being potentially, going toward actuality, it is progressing to that place, that quantity, and that quality where the actualization of its quantity and quality and place lie.[156] And it is due to the same cause too that what already exists and is earth or fire moves toward its own place if there is nothing impeding it. For nourishment too, when nothing prevents it, and what is capable of being made healthy, insofar as nothing restrains it, proceed immediately. But what causes the movement is what produces it at the start, what removed the hindrance, or from which the thing rebounded, as was said in our first accounts,[157] in which we determined that none of these things moves itself.

The cause due to which each of the spatially moving bodies spatially moves, and what moving to its own place is, has now been stated.

4.4
The Differences of Heavy and Light Bodies

We have now to speak about the differences and the coincidental affections pertaining to these. First, then, let us take as determined, as evident to all, that the unconditionally heavy is what sinks below everything else, and the unconditionally light, what rises above everything else—unconditionally, I mean, looking to the kind, and to those things to which both heavy and light do not belong. For example, it is evident that any random quantity of fire spatially moves upward, if no other random

156. Reading καὶ ὅπου.
157. *Ph.* 255ᵇ13–31.

thing prevents it, and one of earth does so downward. And in the same way too a larger quantity does so faster.

But the things to which both heavy and light do belong are heavy and light in another way; for they both sink below and rise above other ones, as air and water do; for neither of these is unconditionally light or heavy; for both are lighter than earth (for any random part of either rises above it), but heavier than fire (for any part whatever of these sinks below it), while in relation to each other, water is unconditionally heavy, and air unconditionally light; for air in whatever quantity rises above water, while water in whatever quantity sinks below air.

But since of the other bodies, some have heaviness, others lightness, it is clear that in every case the cause lies in the difference of their non-composite parts; for some bodies will be light and others heavy as they happen to have more of one and less of the other of these. So it is about these that we must speak; for the other bodies follow along with the primary ones. Which is precisely, as we said,[158] what those thinkers should have done who say that heaviness is due to the plenum and lightness due to the void.

The result, then, is that the same things do not seem to be heavy or light everywhere, because of the difference of the primary parts. I mean, for example, that in air a talent of wood is heavier than a mina of lead, but in water it is lighter. The cause is that all bodies have heaviness except for fire, and lightness except for earth. Earth, then, and whatever contains the most earth, necessarily have heaviness everywhere, water everywhere except in earth, air everywhere except in water and in earth; for in its own space all have heaviness except fire, even air. A sign of this is that an inflated wineskin weighs more than an empty one. So that if something contains more air than earth or water, it may be lighter than something else in water, but heavier in air; for it does not rise above air, but it does rise above water.

That there is an unconditionally light and unconditionally heavy is evident from the following. By "unconditionally light" I mean what always spatially moves upward naturally, and by "unconditionally heavy" what always does so downward, if nothing prevents it; for there are bodies of both sorts, and it is not the case, as some people think, that all bodies have heaviness; besides other people too think that there is something heavy, that is, that always spatially moves toward the center. But in a similar way there is what is light too. For we see, as was said previously,[159] that earthen bodies sink below everything else and spatially move toward the center. But surely the center is definite. If, therefore, there is something that rises above everything else, as fire is observed to spatially move upward even in air itself, the air remaining at rest, it is clear that it spatially moves toward the extremity. So it itself cannot have any heaviness; for, if it did, it would sink below something. And if that were so, there would be something else that spatially moves toward the extremity and rises above all spatially moving things. But as things stand none appears to do so.

158. 309^{b}17–24.
159. 311^{a}19–21.

Therefore, fire has no heaviness at all, nor does earth have any lightness whatever, if indeed it sinks below all other bodies, and what sinks below spatially moves toward the center.

Moreover, that there is a center that the spatial movement of bodies having heaviness is toward, and the spatial movement of light bodies away from, is clear from many considerations.

First, no body can possibly go on spatially moving without limit. For just as nothing impossible can exist, in the same way neither can it come to be. And spatial movement is a process of coming to be from one place to another place.

Next, fire spatially moving upward, and earth and everything having heaviness spatially moving downward, are observed to do so at similar angles. So it is necessary for them to spatially move toward the center. (Whether the resulting movement is toward the center of the earth or toward that of the universe, since their centers is the same point, is for another account.[160]) But since what sinks below all bodies spatially moves toward the center, it is necessary for what rises above everything else to spatially move toward the extremity of the space in which their movement is produced; for the center is contrary to the extremity, and what is always sinking below is contrary to what is always rising above. That is why it is also reasonable that the light and the heavy are two things; for the places are also two, the center and the extremity.

But there is also a place intermediate between these, which is said to be the one in relation to the other; for the intermediate is in a way extremity and center of both.[161] This is why there is also something else, both heavy and light, such as water and air.

And we say that what encompasses pertains to form, what is encompassed to matter. And this distinction exists in every kind; for in fact in [the category] of quality as in that of quantity, there is what is more so form, and what is more so matter. And in the case of what has to do with place it is the same way: up pertains to what is defined, down pertains to matter. So in the case of the matter itself for what is heavy and light, insofar as it is potentially of the one sort, it is matter for what is heavy, insofar as it is potentially of the other sort, matter for what is light. And it is the same matter, but its being is not the same [in the two cases], as in what is capable of being made diseased and what is capable of being made healthy. For their being is not the same; which is why being diseased is not the same as being healthy either.

4.5
The Way in Which the Matter Is One

What has the relevant sort of matter, then, is light and always [spatially moves] upward, and what has the contrary sort is heavy and always [does so] downward. And what has[162] other sorts of matter than these, but ones having in relation to each other

160. 296[b]9–18.
161. Reading ἀμφοτέρων τὸ μεταξύ.
162. Reading τὰ δ'.

what these themselves have unconditionally, has both upward and downward spatial movements.[163] That is why air and water each have both lightness and heaviness, water sinks below everything except earth, and air rises above everything except fire.

But since there is only one body that rises above everything else and only one that sinks below everything else, it is necessary for there to be two others that both sink below some things and rise above others.

So it is also necessary for there to be just as many sorts of matter as of these bodies (namely, four), but in such a way that there is one matter common to all of them—especially if they come to be from each other—though its being is distinct. For there is nothing to prevent there being one or more intermediates between the contraries, as in the case of colors; for intermediate and center are said of things in many ways. **312^{b}1**

Each of the bodies having both heaviness and lightness, then, has heaviness in its own space (while earth has heaviness everywhere), but does not have lightness, except in those bodies in which it rises.

That is also why if a supporting body is removed, each spatially moves to the body next below it, air to the space of water, water to that of earth. But air will not spatially move upward into the space of fire, if the fire is done away with, except by force, just as water is drawn up when its surface becomes one [with that of air],[164] and something draws it upward faster than the water's own spatial movement downward. Nor will water spatially move into the space of air, except in the way just now stated. Earth, on the other hand, is not thus affected, because its surface is not one [with that of water]. That is why water is drawn up into a vessel heated by fire, while earth is not. And as earth does not spatially move upward, neither does fire move downward when the air supporting it is removed; for fire has no heaviness at all even in its own space, just as earth has no lightness. But the two other bodies spatially move downward when the supporting body is removed, because, while what is unconditionally heavy sinks below everything else, what is relatively heavy sinks as far as its own space or as the space of the bodies above which it rises, because of the similarity of matter.

And that it is necessary to make differences equal in number to these bodies is clear. For if there is one sort of matter for all things (for example, void or plenum, or magnitude, or triangles), either all will spatially move upward or all downward, and the other spatial movement will not exist at all. So either nothing will be unconditionally light, if everything causes a balance to incline more downward due to the greater size or number of its constituent bodies, or because there are plenums (we see this, though, and it has been proved, that in the same way as there is something that spatially moves always and everywhere downward, there is something that does so always and everywhere upward); or, if [their matter is] the void or something of

163. Reading φερόμενα.

164. As in the case of evaporation (*Mete.* 346^{b}32–33).

this sort that does so always upward, there will be nothing that does so always downward. Also, there will of course be certain intermediates that spatially move faster downward than earth does; for in a large quantity of air there will be more triangles, or solids, or small [particles]. But it is evident that not one part of air spatially moves downward. It is likewise in the case of lightness too, if one makes the superiority of lightness depend on the matter in question.

If, on the other hand, there are two sorts of matter, how will the intermediates do the things air and water do? (For example, suppose someone were to say that they are void and plenum. Fire, then, is void, because it moves upward, while earth is a plenum, because it moves downward. And air contains a preponderance of fire, water of earth.) For there will then be a quantity of water containing more fire than a small quantity of air does, and a large quantity of air containing more earth than a small quantity of water does, so that some quantity of air will have to spatially move downward faster than a small quantity of water. But this never appears to happen anywhere.

It is necessary, therefore, that just as fire in fact moves upward, because it contains something (for example, void) while the others do not, and earth moves downward, because it contains a plenum, so air moves to its own [place] and above water, because it contains something else, and water downward, because it contains something else again.

But if air and water both contained one [matter], or two matters that will both belong to each, there will be a certain quantity of each that will make water exceed a small quantity of air in [its speed of] moving upward, and air that of water in moving downward, as we have often said.

4.6
Shapes and Movements of Bodies

Shapes are not a cause of unconditional spatial movement downward or upward, but rather of making it faster or slower. And the causes due to which they do so are not difficult to see; for what makes one puzzle now is why a flat piece of iron or lead floats on water, while other smaller and less heavy ones, if they are round or elongated—a needle, for example—spatially move downward, and why it is that certain bodies float because of their smallness, as metal filings and other earthen and dust-like particles do in air.

As regards all three cases, to consider their cause to be as Democritus alleges is not correct. For he says that hot particles spatially moving upward from water hold up flat bodies that have heaviness, but let narrow ones fall through; for only a small number of these particles offer resistance to them. But this should happen more easily in the air, an objection which he himself raises. But he resolves it in a weak way; for he says

that "the surge" does not impel in [only] one direction, meaning by "the surge" the movement of the bodies spatially moving upward.

But since some continuous bodies are more easily divided and others less, and since things capable of dividing them are the same way, some more capable, others less, it is this fact that we must consider to be the cause. What is easily bounded is easily divided, and more so what is more so; and air is more like this than water, water than earth. Also, within each kind, the smaller the quantity, the more easily it is divided and dispersed. But those having breadth remain in place because of covering so large a surface, and because the large quantity is less easily dispersed. Those, on the other hand, that have contrary shapes, because of covering so small a surface, spatially move downward, because the division is easy. And this happens much more easily in air, insofar as it is more easily divided than water.

But since the heavy has a certain strength in accord with which it spatially moves downward, and continuous bodies have one for not being dispersed, these must be pitted against each other; for if the strength of the heavy one exceeds that in the continuous one for not being dispersed and divided, then it will force itself downward faster, while if it is weaker, it will float [on the surface].

Concerning heaviness and lightness, then, and the coincidental affections pertaining to these, let things be determined in this way.

ON COMING TO BE AND PASSING AWAY*

De Generatione et Corruptione

BOOK 1

1.1
Coming to Be, Passing Away, Growth, Withering, and Alteration

But concerning the coming to be and passing away of the things that by nature come to be and pass away, we must determine—alike with regard to all of them—their causes **314ª1**
and accounts. Further, concerning growth and alteration, we must determine what each is, and also whether we must suppose that the nature of alteration and of coming to be are the same, or separate, just as there is a distinction regarding their names. 5

Among the ancients, some say that what is called "unconditional coming to be" is an alteration, others that alteration and coming to be are distinct. For those who say that the universe is some one thing and make everything come to be from one thing, must of necessity say that coming to be is alteration and that what, in the strict sense, comes to be is altered. On the other hand, for those who posit more than one 10
[sort of] matter, like Empedocles, Anaxagoras, and Leucippus, they are two distinct things. And yet Anaxagoras was ignorant of the proper sense of his utterance; for he says, at any rate, that coming to be and perishing are the same as altering, but says that the elements are many, just as others also do. For Empedocles makes the 15
corporeal elements four, but in all, together with those that move them, [they] are six in number, while for Anaxagoras they are unlimited, as they are for Leucippus and Democritus. For he posits the uniform things as elements—for example, flesh, bone, marrow, and each of the others where a part is synonymous with the whole. 20
Democritus and Leucippus, by contrast, posit indivisible bodies, unlimited in number and shape, from which all the others are composed, differing in relation to each other in the ones from which they are composed and in the position and order of these. For it is evident that the followers of Anaxagoras and those of Empedocles say contrary things. For the latter says that fire, water, air, and earth are the four elements, and that 25
these—rather than flesh, bone, and the uniform things of this sort—are simple; while for the former ones, the uniform things are simple and elemental, while earth, fire, water, and air are composites; for they are a universal seedbed of the uniform things.

* Translated by C. D. C. Reeve. Text: M. Rashed, *Aristote: De la Génération et la Corruption* (Paris, 2005).

314b1 Those, on the other hand, who construct everything from one thing, must of necessity say that coming to be or passing away is an alteration; for the underlying subject always remains one and the same. And this is the sort of thing that we say alters. Those, by contrast, who posit a plurality of kinds must distinguish alteration from coming to be; for, for them, coming to be and passing away occur when things come together and undergo dissolution. That is why Empedocles in fact speaks in this way, saying that:

> Nothing that is has a nature . . .
> But rather there is only mixing and separating of things mixed.[1]

That the statement is properly in keeping with what they posit, then, is (one might almost say) clear; that is why they speak in this way. But it is necessary for them too to say that alteration is something other than coming to be, yet this is impossible according to what they do say.

That we are speaking correctly in saying this is easy to see. For just as, while the substance remains at rest, we see in it a change with respect to magnitude, which is called "growth and withering," in the same way we see alteration occurring. Nonetheless, on the basis of what is said by those who make the starting-points more than one, alteration is impossible. For the affections with respect to which we say that this occurs are the differences of the elements—I mean, for example, hot cold, white black, dry wet, soft hard, and each of the others. Just as Empedocles in fact says:

> Sun, white to see and everywhere hot . . .
> And rain everywhere dark and cold.[2]

And he determines the remaining ones in a similar way. So if it is not possible for water to have come to be from fire or earth from water, neither will it be possible for anything to have come to be black from white or hard from soft. And the same argument will also apply to the others. But it is this, as we said, that alteration consists in.

It is also evident from this that a single matter must always be supposed for contraries, whether the change is with respect to place, with respect to growth and withering, or with respect to alteration. Further, it is equally necessary that this is [the case with matter] and that alteration is; for if there is alteration, the underlying subject is also
315a1 one element and there is one matter for all the things that admit of change into each other, and if the underlying subject is one, there is alteration.

Empedocles, then, seems to contradict both the things that appear to be so and himself. For while he says that none of the elements comes to be from another, but rather that all the other things come to be from them, at the same time, when he has made the whole of nature, except strife, come together into one, he says that from

1. B8 DK.
2. B21 DK.

this one each thing again comes to be. So it is clear that it was by being separated out from some one thing by certain differences and affections that something came to be water and something else fire, just as, he says, the sun is white and hot, earth heavy and hard. If, then, these differences are subtracted (for they can be subtracted; since they came to be, at any rate), it is clearly necessary both for earth to come to be from water and water from earth, and similarly for each of the others, not only *then* but also *now*, since they change, at any rate, with respect to their affections. And, from what he has said, they can be added together as well as separated again, especially since strife and love are still fighting with each other. Which is precisely why even *at that time* they came to be from one thing; for the universe was certainly not fire *and* earth *and* water when it was one thing.

But it is also unclear whether he should posit as a starting-point the one or the many—I mean, fire, earth, and the co-ordinates of these. For insofar as the one is like the underlying matter from whose changing due to movement earth and fire come to be, the one is elemental. On the other hand, insofar as the one comes to be from composition by a coming together of the latter, and they through its dissolution, they are more elemental and prior in nature.

1.2
Unlimited Divisibility of Magnitudes

It is about both unconditional coming to be and passing away in general, then, that we must speak, saying whether it exists or does not exist and in what way, and about the other sorts of movements—for example, growth and alteration. Plato, on the other hand, investigated only coming to be and passing away, in what way they belong to things, and not all coming to be but [only] that of the elements—he said nothing about the way flesh, bones, or anything else of that sort come to be. Further, neither did he investigate alteration or growth, nor what way they belong to things. In general, no one seems to have paid anything besides superficial attention to these matters except for Democritus. By contrast, he seems to have given thought to all of them, in a way that was different from his times. For about growth none of them has determined anything, as we are saying, except what a random person might say, **$315^{b}1$** namely, that things grow by the addition of like to like, although nothing about the way this occurs. Nothing either about mixture, nor about (one might almost say) any of the others—for example, affecting and being affected, or in what way one thing affects and another is affected in natural productions. Democritus and Leucippus, however, having posited that shapes produce alteration and coming to be from these: coming to be and passing away by their aggregation and disaggregation, alteration by their order and position. But since they thought that the truth lies in what appears to be so, and the things that appear to be so are contraries and unlimited [in number], they made the shapes unlimited [in number], so that, due to changes in its

composition, the same thing seems to be contrary ways to two different people and, due to the mixing in of something small, undergoes a transposition, and, one particle being shifted, appears wholly otherwise; for *tragô[i]dia* and *trugô[i]dia* come to be from the same letters.[3]

But since it seems to pretty much everyone that coming to be and alteration are distinct, and that while some things come to be and pass away by being aggregated and disaggregated, they alter by changing their affections, it is having turned one's attention to these that one must get one's theoretical grasp on the issues. For these involve puzzles that are at once many and reasonable. For if coming to be is aggregation, many impossible things follow. Yet there are other opposing arguments on the other side, and ones not easy to resolve in a puzzle-free way, that it cannot possibly be anything else. If, alternatively, coming to be is *not* aggregation, either there is no coming to be at all or it *is* alteration; or else this [puzzle] too, difficult though it is, is necessary to try to resolve.

A starting-point, however, of all these matters is whether the beings come to be, alter, grow, and undergo the contraries of these, the primary magnitudes being indivisible, or whether there is no indivisible magnitude; for this makes the greatest difference. And, again, if there are [indivisible] magnitudes, are they bodies, as Democritus and Leucippus say, or planes, as in the *Timaeus*?[4]

This, as we have also said elsewhere,[5] is unreasonable in its own terms, namely, to resolve things no further than to planes. That is why it is more reasonable for there to be indivisible bodies. Although this too involves many unreasonable things. Nonetheless, with indivisible bodies it is possible to produce alteration and coming to be, causing a transposition in what is the same by "turning" and by "contact" and by the differences of shapes, precisely in the way Democritus does. (It is also why he says that color does not exist, for it is by turning that there is coloration.) But for those who divide things into planes this is no longer possible; for, by putting together, nothing comes to be except solids. In fact, they do not even attempt to generate any affection at all from them.

The cause of our being incapable of taking a comprehensive view of the agreed-upon facts is lack of experience. That is why those who are more at home among natural things are better able to posit the sort of starting-points that can string together a good many of these, while those who on the basis of their many [logico-linguistic] arguments do not get a theoretical grasp on the facts, but look at only a few, make their declarations too recklessly. One can see from this too how much difference there is between investigating in the way appropriate to natural science and in a logico-linguistic way; for concerning the existence of indivisible magnitudes, the latter lot

3. *Trugô[i]dia* is a rare word meaning "comedy." The idea is that the two words come from the same letters and then one particle, namely, "a," gets "shifted" when "u" gets mixed in and replaces it.

4. 52d–57d.

5. E.g., *Cael.* 299ᵃ6–11.

say that the triangle-itself will [otherwise] be many, while Democritus would appear to have been convinced of this by arguments that are proper to and appropriate to natural science. What we are saying will be clear as we go on.

For a puzzle would be involved if one were to posit that some body and magnitude is divisible at every point, and that this is possible. For what precisely will what escapes the division be? For if it is divisible at every point, and this division is possible, it could also be in the state of being divided at every point at the same time, even if it had not been divided up at the same time (and even if this latter did happen, there would be nothing impossible involved). Hence the same applies also at the mid-point and, in general too, if it is naturally divisible at every point; then, if it is [in fact] divided up, nothing impossible will have happened, since not even if it is divided at a hundred million points is there any impossibility—and yet perhaps no one would so divide it.

Since, therefore, the body is like this at every point, let it have been divided [at them]. What, then, will remain? For it cannot be any magnitude; for then there will be something undivided, but it was said to be divided at every point. But then, if there will be no body and no magnitude remaining, but there will be division, either the body will consist of points, and what it is composed of will be without magnitude, or there will be nothing remaining at all, so that it would come to be from, and be composed of, nothing, and the totality, then, would be nothing but an appearance. Similarly, even if it consists of points, there will be no quantity. For when the points were in contact and the magnitude was one and they were together, they did not make the totality any greater. For when it was divided into two or more, the totality was not greater or smaller than before, so that even if they are all put together, they will produce no magnitude. But then even if, during division, something is produced like sawdust from the body, and in this way some body is removed from the magnitude, the argument is the same: it is divisible in some way. But if what is **316^{b}1** removed is not a body but some separable form or some affection, and the magnitude consists of points or contacts affected by this, it is absurd for a magnitude to be composed of components that are not magnitudes.

Further, the points will be somewhere and they will be immovable or in movement; also, a single contact is always between two things, as there is always something beyond the contact, the division, and the point.

If, then, someone posits that any body whatever of any magnitude whatever is divisible at every point, these are the things that follow.

Further, if I had divided and had put back together the piece of wood, or anything else, it would again be equal and one. Hence the same clearly applies if I cut the wood at any point whatever. Therefore, it is at every point that it has been potentially divided. What, then, is there beyond the division? For if there is also some affection, how is it dissolved into these and how does it come to be from these? And how are these separated?

So, if indeed it is impossible for magnitudes to be composed of points or contacts, it is necessary for there to be bodies and magnitudes that are indivisible. Nonetheless, for those who posit these, no less impossible things follow. These have been investigated elsewhere.[6] But an attempt must be made to resolve them. That is why the puzzle must be stated again from the start.

That every perceptible body is divisible at every point and indivisible is no absurdity; for being divisible will belong to it potentially, while being indivisible will do so actually. But that it should be potentially divisible at every point at the same time would seem to be impossible. For if it were possible, it could also come about (not so as to be at the same time both in actuality indivisible and divided, but so as to be divided at every point). Therefore, there will be nothing remaining, and the body will have passed away into something incorporeal, and could come to be again either from points or from something that is nothing at all. And how is this possible? Yet that it *does* get divided into magnitudes that are separable, and into ones that are always smaller and smaller, and into ones that are at a distance from each other and separated, is evident. But division part by part could not go on without limit and neither can a body be divided at every point at the same time (for that is not possible), but only up to some [limit]. Therefore, it is necessary for it to contain indivisible magnitudes that are invisible—especially if coming to be and passing away are going to be by aggregation and disaggregation.

This, then, is the argument that seems to make it necessary for there to be indivisible magnitudes. And that it contains a hidden fallacy, and where it is hidden, we now explain. For since no point is contiguous to another point, there is one way in which being divisible at every point does belong to magnitudes, and another in which it does not. When this divisibility is posited, it seems that there is a point both anywhere and everywhere, so that it is necessary for the magnitude to be divided into nothing; for there is a point everywhere, so that the magnitude is composed of contacts or points. The way, however, in which divisibility does belong at every point is that anywhere at all there is one point in whichever direction, and that all points are like each; but there are not more than one [there]; for points are not successive, so that [it does not belong] at all points; for if a magnitude is divisible at the mid-point, will it also be divisible at a contiguous point? For cut is not contiguous to cut or point to point. And this cut serves as a division or a join.

So there is both disaggregation and aggregation, but neither into indivisibles and from indivisibles (for the impossibilities involved are many) nor in such a way that division has occurred at every point (for [only] if point were contiguous to point would this have been so). Instead, disaggregation is into small parts and then smaller ones, and aggregation is from smaller ones.

But it is not the case that unconditional and complete coming to be and passing away are defined by aggregation and disaggregation, as some say, while change in

6. *Ph.* 231ᵃ21–ᵇ18, *Cael.* 303ᵃ3–ᵇ8.

what is continuous is alteration. On the contrary, this is where all the mistakes are made. For unconditional coming to be and passing away do not occur by means of aggregation and disaggregation, but are when a whole changes from a *this* to a *this*. Others think that all this sort of change is alteration, but there is a difference; for within the underlying subject there is something corresponding to the account and something corresponding to the matter. When, then, the change is in these, there will be coming to be or passing away. But when it is in the affections and is coincidental, there will be alteration.

By being disaggregated and aggregated, things do become more [or less] easily capable of passing away. For the smaller raindrops are divided, the faster they become air, while if they have been aggregated, they do so more slowly. This will become clearer in what follows. For now, however, let us take this much as determined, namely, that it is impossible for coming to be to be aggregation, as some people say it is.

1.3
Unconditional Coming to Be

These things having been determined, we must first get a theoretical grasp on whether there is anything that comes to be and passes away unconditionally, or whether strictly speaking nothing does, but always it is something that comes to be and it comes to be from something [else]—I mean, for example, coming to be healthy from being sick, and sick from being healthy, or small from large and large from small, and all the others in the same way.

For if there is going to be unconditional coming to be, something would come **317^{b}1** to be from not being unconditionally, so that it would be true to say that not being belongs to some things. For non-unconditional coming to be something is from not being something (for example, from not being white or not being beautiful), while unconditional coming to be is from unconditional not being. But "unconditionally" signifies either what is primary in each category of being, or what is universal and encompasses everything. If, then, it signifies the first, substance is going to come to be from not substance. But what neither substance nor thisness belongs to, clearly none of the other categories does either—for example, quality, quantity, or place; for otherwise affections would be separable from substance. If, on the other hand, it signifies wholly not being, it will be the universal denial of everything, so that what comes to be will necessarily come to be from nothing.

The puzzles concerning these issues have been gone through and determined at greater length in other accounts.[7] But let us in a summary way now state again that in one way it is from what is not that a thing comes to be unconditionally, although

7. *Ph.* 1.6–9.

in another way it is always from what is; for what potentially is but actually is not must of necessity preexist, and it is spoken of in both ways. But even when these distinctions have been drawn, a wondrous puzzle remains, which must be gone through again, as to how unconditional coming to be is possible, whether from what is potentially a substance or in some other way. For one might raise a puzzle as to whether there is a coming to be of substance—that is, of the this—which is not [a coming to be] of the thus qualified, the thus quantified, or the where placed. And it is the same way too as regards passing away. For if a [this] something comes to be, clearly there will be potentially, but not actually, some substance from which its coming to be will [proceed] and into which what passes away necessarily changes.[8] Will, then, any of the others actually belong to this? I mean will what is only potentially a this and a being, but unconditionally is neither a this nor a being, have, for example, a quantity, a quality, or a somewhere? For if it has none, but all potentially, it follows that what in this way is not is separable, and further, what the first philosophers feared most of all has come to pass, namely, the coming to be of something from nothing preexisting. On the other hand, if being a this something or a substance is not going to belong to it, while some of the other things are going to, affections, as we said, will be separable from substance.

It is necessary, then, to study these issues as much as possible, and on what the cause is of there always being coming to be, both unconditional and partial.

318ᵃ1 But since there is one cause that we say is the starting-point of movement, and another one that is the matter, it is the latter sort of cause that must be spoken about. For the former has already been spoken about in our accounts concerning movement,[9] where we said that there is, on the one hand, what is immovable for all time and, on the other, what is always in movement. The first of these—the immovable starting-point—is work for the other and prior philosophy to discuss. Concerning the second, the one that moves the other things through being itself continuously moved, it must be determined later[10] which of the things said to be particulars is a cause of this sort. But for now let us speak about the cause posited as being of the material form, due to which passing away and coming to be never fail to occur in nature; for at the same time as this becomes clear, we will perhaps also get clear about what is now puzzling us, as to how precisely one should in fact speak too about unconditional passing away and coming to be.

Enough of a puzzle is in fact involved in what the cause is of the unbroken continuity of coming to be, if indeed what passes away disappears into what is not, and what is not is nothing; for what is not is neither a something, nor a quality, nor a quantity, nor a somewhere. If indeed, then, some one of the beings is always disappearing, why precisely has not the universe been consumed long ago and vanished,

8. Reading ἐξ ἧς ἡ γένεσις ἔσται καὶ εἰς ἣν ἀνάγκη μεταβάλλειν τὸ φθειρόμενον.
9. *Ph.* 5, 6, and 8.
10. 336ᵃ23–ᵇ12.

if, at any rate, each of the things coming to be comes to be from something limited? For of course it is not because what each comes to be from is unlimited that it does not fail to occur; for this is impossible; for nothing is actively unlimited, and is potentially so only in the direction of division, so that the only sort of coming to be that never fails to occur would be due to what comes to be always being smaller. But as things stand this is not what we see.

Is it, then, because the passing away of one thing is the coming to be of another, and the coming to be of one thing is the passing away of another, that change is necessarily unceasing? As regards the existence of the coming to be and likewise of the passing away of each of the beings, this should be thought enough of a cause.

But why precisely some things are said to come to be and pass away unconditionally and others not unconditionally must be investigated again, if indeed the same thing is the coming to be of this and the passing away of that, and the passing away of this is the coming to be of that; for this seeks some account. For we say that passing away occurs now unconditionally, and not only that *this* passes away; also that this is a case of coming to be unconditionally, and this of passing away unconditionally. On the other hand, if this comes to be something, it does not come to be unconditionally; for we say that a person who learns comes to be scientifically knowledgeable, not that he comes to be unconditionally.

We often make a distinction by saying that some things signify a this something while others do not; what is being sought is a consequence of this. For it makes a **$318^{b}1$** difference what the changing thing changes into—for example, perhaps the route that leads to fire is a coming to be unconditionally, but a passing away of something (of earth, for example), while the one to earth is a coming to be of something (but not an unconditional coming to be[11]), but an unconditional passing away (of fire, for example). Parmenides speaks of a pair like this, saying that what is and what is not are fire and earth. Whether this pair or another of the same sort is posited makes no difference; for we are seeking the way it happens, not what is being posited. And the route that leads to unconditional not being is unconditional passing away, while the one that leads to unconditional being is unconditional coming to be. Of the pair in terms of which the distinction is made, whether fire and earth or some other, one will be what is and the other what is not. This, then, is one way in which unconditional coming to be and passing away will differ from the one that is not unconditional.

Another way is by the sort of matter involved; for if the differences in the matter signify more of a this something, the matter is more of a substance, while if they signify a privation, it is more of a non-being. For example, hot is a certain [positive] predicate and a form, and cold is a privation, and earth and fire differ by these very differences.

But it seems to ordinary people that the difference is more one of being perceptible and being imperceptible; for when the change is to perceptible matter, they say that

11. Reading γένεσις δ᾽οὐχ ἁπλῶς.

it is a coming to be, when to matter that is unapparent, a passing away; for they distinguish being from non-being by what they perceive and do not perceive, just as, for example, what is scientifically knowable is [said to be] being, the unknowable [said to be] not being; for perception has the capacity of scientific knowledge. Hence, just as they think themselves to live and be in virtue of their perceiving or being capable of perception, so it is too with things. And in a way they are tracking the truth, though what they say is not itself true. Indeed, unconditional coming to be and passing away turn out one way in accord with belief and another in accord with truth; for, in accord with perception, wind and air are less a this something and a form than earth is (that is why they say that what passes away unconditionally changes into these, while coming to be occurs when there is change into something tangible, that is, into earth), while, in accord with truth, they are more so.

The cause, then, of there being unconditional coming to be that is the passing away of something, and of unconditional passing away that is the coming to be of something, has now been stated; for it is due to the matter differing, either in virtue of its being a substance or not, or of its being more a substance or not, or because of the matter from which or to which [it changes] being more perceptible in the one case and less so in the other.

But what is the cause due to which some things are said to come to be unconditionally, others only to come to be something, and not in virtue of the coming to be of one thing from another, in the way we have just now stated? For up to now we have determined only this much: why precisely, when every coming to be is the passing away of something else and every passing away the coming to be of a distinct thing, we do not in the same way attribute the coming to be and passing away to the changing things. But the puzzle that was mentioned later[12] was not the one gone through, but was precisely why what learns is not said to come to be unconditionally but to come to be scientifically knowledgeable, while what is born is said to come to be unconditionally. This, then, is determined by their categories; for some things signify a this something, some a quality, some a quantity. Those that do not signify a substance are not said to come to be unconditionally, but to come to be something.

Nevertheless, in every case, coming to be is said in accord with one of the two columns [of contraries]—for example, in substance, if it is fire, but not if it is earth, in quality, if it is scientifically knowledgeable, but not if it is lacking in scientific knowledge.

The unconditional coming to be of some things, then, but not of others, both in general and in the case of substances themselves, has now been spoken about; as has why the underlying subject is the cause, as matter, of the continuous occurrence of coming to be, namely, because it is capable of changing from contrary to contrary, and because in the case of substances the coming to be of one thing is always the passing away of another, and the passing away of one thing, the coming to be of another.

12. 318ᵃ27–35.

Moreover, there is no need to be puzzled either as to why there is coming to be when things are always passing away; for just as people speak of something unconditionally passing away when it passes into imperceptibility (that is, into what is not), similarly they say that something comes to be from what is not when it emerges from imperceptibility, whether the underlying subject is something or is not anything. So in the same way as something comes to be from what is not, it also passes away into what is not. It makes perfect sense, then, that it does not fail to occur; for coming to be is the passing away of what is not and passing away the coming to be of what is not.

But this *what unconditionally is not*, is it one of the two contraries—for example, is earth (that is, what is heavy) what is not, and fire (that is, what is light) what is—or not, but rather earth too is what is, while what is not is the matter of earth and fire alike? Also, is the matter of each of these distinct? Or, in that case, is it that they would not come to be from each other, or from contraries (for it is to these that the contraries belong, namely, fire, earth, water, air)? Or is the matter in one way the same, and in another way distinct? For the thing (whatever it is) by being which it underlies is the same, but its being is not the same.

About these issues, then, let this much be said.

1.4
Alteration

Let us now say what the difference is between coming to be and alteration, since we say that these changes are distinct from each other. Since, then, the underlying subject is one thing and the affection that is naturally said of the underlying subject is another, and there is a change of each of them, there is alteration when the underlying subject, which is perceptible, while remaining [the same], changes in its own affections, which are either contraries or intermediates (for example, the body is healthy and again sick, while remaining, at any rate, the same [body], and the bronze is round and at another time angular, while being the same [bronze]). But when a whole changes, while nothing perceptible remains as the same underlying subject, but rather is like when blood comes from the whole of the semen [changing], or air from water, or water from the whole of air, something of this sort is then a coming to be, and a passing away of the other thing, especially if the change is from something imperceptible to something perceptible, either to touch or to all the perceptual modalities—for example, when water comes to be from or passes away into air (for air is fairly imperceptible).

In the latter cases, if some affection of a contrariety remains the same in what came to be and in what passed away (for example, when water comes to be from air, if both are transparent or cold), the other thing to which it changes must not be an affection of this former one. Otherwise, the change will be an alteration. For example, the

musical human passed away, and the unmusical human came to be, but the human remains the same. If, then, musicality and unmusicality were not intrinsically affections of this latter, there would be a coming to be of the one and a passing away of the other. That is why these are affections of the human, though of unmusical human there is a coming to be and of musical human a passing away. But as things stand this is an affection of the underlying subject. That is why cases of this sort are alteration.

When, then, the change of a contrariety is with respect to quantity, there is growth and withering; when it is with respect to place, spatial movement; when with regard to an affection and a quality, alteration; but when nothing remains of which the other [resulting thing] is an affection, or, in general, a coincident, there is coming to be, and, on the other hand, passing away.

Matter in the most strict sense is the underlying subject receptive of coming to be and passing away, but in a certain way that of the other changes too, because all underlying subjects are receptive of certain contrarieties.

Concerning coming to be—whether or not it exists, and in what way it exists—and alteration, let things be determined in this way.

1.5
Growth

It remains to speak about growth, in what respect it differs from coming to be and alteration, and how each of the things that grow grows and how any one of the things that withers withers. It is necessary, then, to investigate first whether their difference from each other lies [only] in what they concern—for example, because the change is from a this to a this, that is to say, from a potential substance to an actual substance, it is coming to be; because it has to do with magnitude, growth; with affection, alteration (the latter two being a change from potential to actual of the things mentioned [namely, magnitude and affection])—or whether the mode of the change differs too; for it is evident that while what alters does not of necessity change with respect to place, and neither does what is coming to be, what grows and what withers does, but in another way than what spatially moves. For what spatially moves changes its place as a whole, while what grows does so like metal that is beaten out; for while it remains where it is, its parts change with respect to place, although not as the parts of a [revolving] sphere do; for these change within a place of the same magnitude, while the whole remains where it is, while the parts of what grows occupy an ever larger place, what withers always an ever smaller one. It is clear, then, that the change in the case of what is coming to be, what is altering, and what is growing differs not only in what it has to do with but also in its mode.

But what the change has to do with in the case of growth and in that of withering (granted that growth and withering seem to have to do with magnitude), how should it be supposed to be? Is it from something potentially a body and a magnitude, but

actually incorporeal and without magnitude, that a body and a magnitude come to be? But since this also admits of being said in two ways, in which of them does growth come to be? Is the matter from which it comes itself an intrinsically separated thing, or does it exist in another body? Or are both of these impossible? For, if it is separated, it will either occupy no space, like a point, or it will be a void or an imperceptible body. Of these, one is impossible, while the other makes it necessary for it to be in something; for what comes to be from this matter is always going to be somewhere, so that the matter too must be somewhere, either intrinsically or coincidentally. But then if it is going to be in something, if it is separated in such a way as not to belong to it either intrinsically or coincidentally, many impossibilities will follow. I mean, it would be as if water comes to be from air, not because the water is what changes, but because the matter of the air is present in the water like in a vessel. For then nothing would prevent there from being an unlimited number of matters [in it], so that they might actually come to be [from it]. Further, it is evident that air does not come to be from water in this way, as if coming out from something that persists. Therefore, it is better in every case to make the matter inseparable, as being the same and one in number, though not one in account. But then, points cannot be posited as the body's matter either, and neither can lines, due to the same cause. The matter is what points and lines are limits of, and it is something that can never exist without affections and without shape.

One thing unconditionally comes to be from another, as has been determined elsewhere, and always as a result of something actually being, either the same in form or the same in kind (for example, fire as a result of fire, or human as a result of human), or else as a result of an actuality; for a hard thing does not come to be as a result of a hard thing. But since there is also matter for corporeal substance, and this is already the matter for *this* sort [of body] (for there is no body that is common), the same one will also be matter for magnitude and affection—separable in account, but not separable in place, unless the affections too are separable.

It is evident, then, from the puzzles gone through that growth is not a change from something that potentially has magnitude, but that actually has no magnitude; for then the void would be separable, and that this is impossible has been stated previously elsewhere.[13] Further, change of *this* sort would not be special to growth but would belong to coming to be generally. For growth is the increase of a preexisting magnitude, and withering its diminution. That is why, indeed, what is growing must have some magnitude. So growth must not be regarded as being from matter without magnitude to actual magnitude; for this would instead be the coming to be of a body, not growth.

We must, then, as if undertaking the investigation from the start, take up in greater detail the question of what sort of thing growth or withering is whose causes we are seeking. It is evident, then, that when a thing grows each and every part of it has

13. *Ph.* 4.6–9.

grown, and similarly when a thing withers each and every part has become smaller, further, that a thing grows by something that is added, and withers by something that is subtracted. But it is necessary that growth be either by something incorporeal or by a body. If, then, it is by something incorporeal, there will be a separable void (but it is impossible for the matter for magnitude to be separable, as was said previously[14]), while if it is by a body, there will be two in the same place, the one that grows and the one that grows it; but this too is impossible.

But then neither is it possible to say that growth or withering comes about just as when air comes from water; for in that case the mass has become greater, but this is not in fact growth but a coming to be of the thing the change will be to, and a passing away of its contrary, though not a growth of either. Instead, either nothing grows or if [anything does] it is something that belongs jointly to both what passes away and what comes to be—for example, if body does. But the water has not grown, neither has the air; rather, the one has passed away and the other has come to be, though the body involved has grown—if indeed anything has. But this too is impossible; for one must preserve in the account the things that belong to what is growing and what is withering. And these are three in number: one, each and every part of what is growing is larger (for example, if it is flesh, of flesh); second, something is added to it; and third, what grows is preserved and remains; for while in the case of something unconditionally coming to be or passing away the thing does not remain, in those of alteration and growth or withering, what grows or alters does remain the same, although in the first the affection and in the second the magnitude does not remain the same. If, then, the change just mentioned is to be growth, it would be possible for something to grow though *nothing* was added to it or remained (and to wither though nothing has been subtracted) and what grows did not remain. But this must be preserved; for growth was posited[15] to be like this.

But someone might also raise a puzzle as to what it is that grows. Is it that to which something is added? For example, if someone's calf grows, it becomes larger, but that by which it grows, the nourishment, does not. Why is it, then, that not both have grown? For the thing that grows and the one by which it grows are both larger, just as when one mixes wine with water; for one has more of each of the two alike. Is it because the substance of the one remains, while that of the other—the nourishment—does not? [No,] since in the other case too it is what masters in the mixture that it is said to be—for example, that it is wine; for the compound mixture **321[b]1** does the work of wine but not that of water. It is the same way too in the case of alteration, if being flesh remains and the what-it-is, but an intrinsic affection that did not belong to it previously [now] belongs to it—it has altered. [Response.] But that by which it is altered, though it is sometimes not affected at all, sometimes has also been altered. [Response.] But what alters it, that is, the starting-point of the movement,

14. 320[a]27–[b]25.
15. 321[a]17–22.

is within what grows and what is altered, because the mover is in these. Since in fact what enters could sometimes become larger together with the body that has enjoyed it—for example, if having entered it became breath. But it passes away, surely, having been thus affected, and the mover is not in it.

Since the puzzles about this have been sufficiently gone through, it is also necessary to try to find a resolution of the puzzle, while preserving the fact that what grows remains and grows by something added (and withers by something subtracted), and further, that each and every perceptible point [in it] has become larger (or smaller); and that the [growing] body is not a void, nor are two magnitudes in the same place, nor does it grow by anything incorporeal. The cause must be grasped by first making two distinctions: one is that non-uniform things grow by the growth of uniform things (for each one is composed of these); the next is that flesh, bone, and each part of this sort is twofold, just as are the other things that have an in-matter form; for both the matter and the form are said to be flesh and bone.

The growth of each and every part [and what is such by] something added is possible with respect to the form, but with respect to the matter it is not possible; for it must be understood as if someone were measuring out water by the same measure; for what comes to be is always one thing and then another. And this is how the matter for flesh grows, and not by each and every part being added to, but rather some flowing out and some added to each and every part of the figure and the form. This is more clear in the case of non-uniform things—for example, a hand, because it grows proportionally; for in their case it is more clear that the form is distinct from the matter than in the case of flesh and uniform things. That is also why a corpse would seem still to have flesh and bone more than a hand and an arm. So there is a way in which each and every part of flesh grows and a way in which it does not. For with respect to the form there has been addition to each and every part, but not with respect to the matter. The whole, however, has become larger by the addition of something called "nourishment," that is, of a contrary [to flesh] changing to the same form—for example, if wet were to be added to dry, and, having been added, were to be changed and become dry; for in one way like grows by like, in another way by unlike.

One might raise a puzzle as to what sort of thing that by which something grows must be. It is evident, then, that it must be potentially that thing—for example, if it is flesh, potentially flesh. Actually, therefore, it is something else. This having passed away, then, has become flesh. Not, though, this thing intrinsically (for that would be coming to be, not growth), but rather what grows by this.[16] But what, then, is the affection of this thing by which the thing grows? Has it been mixed in it, as if one were to pour water into wine that was able to make what is mixed in it into wine, as fire takes hold of the combustible—is it in this way that the growth-producer, which

16. Suppose some nourishment N becomes flesh F_1. N cannot do this intrinsically, since it can only do it by being digested and transformed into F_1 by an animal already possessed of flesh F_2, which thereby grows by the addition of F_1.

is present in what grows (that is, in what is actually flesh), makes what is potentially flesh into actual flesh when added to it? In that case, then, [it is due to the two] being together; for if [it happens when they are] separate, it is coming to be. For one can make fire in this way, namely, by putting logs on a preexisting fire. In this way, then, it is growth, but when the logs themselves are set on fire, it is coming to be.

A quantity, taken universally, however, does not come to be any more than does an animal that is neither a human nor any other of the particular ones (as universal is here, quantity is there). Instead flesh or bone does, or hand (that is, the uniform components of these). And what is added is in fact a certain quantity of something, but not a quantity of flesh. Insofar, then, as it is potentially both together—for example, so-and-so-much flesh—there will be growth by this; for it must have become both a certain quantity and flesh. But insofar as it is potentially flesh alone, it nourishes; for this is how nourishment and growth differ in account.

This, then, is why something is nourished for as long as it is preserved, even if it withers, but is not always growing. It is also why nourishment and that by which something will grow, though they are the same, are distinct in being; for insofar as what is added is potentially so-and-so-much flesh, it is a growth-producer of flesh, but insofar as it is potentially flesh alone, it is nourishment. But this form without matter, like a pipe, is a certain in-matter capacity. And if some matter were added that is potentially a pipe, and that also has the relevant quantity potentially, these[17] [pipes to which it is added] will be bigger pipes. But if it is no longer capable of producing this [that is, the growth of pipes], but is like water continually mixed with wine, which ends up by making it watery, indeed water, then it will produce withering of the quantity. The form, though, remains.[18]

1.6
Contact

322b1 But since it is necessary first to speak about the matter and the so-called elements, saying whether there are any or not, and whether each is eternal or in some way they come to be, and if they do come to be, whether they all come to be from each other in the same way or whether one among them is primary—before this it is necessary to speak about things that are now said in an indefinite way. For all the thinkers, both those for whom the elements come to be and those for whom things come to be from them, make use of both disaggregation and aggregation and affecting and being affected.

Aggregation is mixing. But what we mean by "mixing" has not been determined in a perspicuous way. Moreover, neither alteration nor disaggregation and aggregation is

17. Reading οὗτοι.
18. Reading τὸ δ' εἶδος μένει here.

possible without something affecting and something being affected; for in fact those who posit several elements make them come to be by affecting and being affected, and for those who make them come to be from one it is necessary to mention the affecting. And in this regard Diogenes [of Apollonia] says correctly that if all things did not come from one, they would not be able to affect and be affected by each other, for example, for the hot to be cooled and for it in return to be heated; for heat and coldness do not change into each other, but rather it is clear that the underlying subject does. So things in which there is affecting and being affected necessarily have a single underlying nature. But it is not true to say that everything is of this sort, but only the ones in which there is [affecting and being affected] by each other.

But surely if we are to get a theoretical grasp on affecting and being affected and one on mixing, it is necessary to get one on contact as well; for affecting and being affected in the strict sense is not possible for things that are not in contact, and neither is mixing possible for those that are not first in a certain sort of contact. So we must determine three things; what contact is, what mixing is, and what affecting is.

Let us take the following as a starting-point. For it is necessary for the beings for which there is mixing to be capable of contact with each other, and the same holds also for those things, where, in the strict sense, one affects and the other is affected. That is why we must first speak about contact. Just as pretty much each of the other names is said of things in many ways, some homonymously, others because one or other of the two derives from a distinct prior one, this is how it is with "contact." Nonetheless, "contact" said in the strict way belongs to things that have position, and position belongs to the very ones that also have place; for even to mathematical objects contact and place are assigned equally, whether each of them exists in separation or in some other way. If, then, as was determined previously, making contact is having the extremities together, those things make contact with each other which are definite magnitudes having size and position that have their extremities together. And since whatever has a position also has a place, and the primary difference of place is up and down, and other opposites of this sort, all things that make contact with each other will have heaviness or lightness, either both or one of the two. And things of this sort are affectable and capable of affecting. So it is evident that the sorts of things that naturally make contact with each other are definite magnitudes whose extremities are together that are capable of moving and being moved by each other.

But since the mover does not [always] move the moved in the same way, but one mover moves by being itself moved, and another while being immovable, it is clear that we must speak in the same way about the affecter; for the mover is said to affect something and the affecter to move something.

Nonetheless, there is a difference and a distinction that must be made. For not every mover can affect something, if indeed we contrast the affecter with the affected, and apply this to those things whose movement is an affection—an affection being that with respect to which a thing alters, such as white and hot. In other words, moving is wider in extension than affecting is.

But this point, at all events, is evident, namely, that there is a way in which the movers will make contact with the things they move and a way in which they will not. Still, the universal definition of making contact applies to things having position, one of which is capable of causing movement and the other capable of being moved; while [that of making contact] with each other applies to things capable of being moved and capable of moving, between which there is affecting and being affected. For the most part, to be sure, what makes contact makes contact with something that makes contact with it; for in fact pretty much all the movers we meet move by being moved, and in these cases it is necessary and evident that what makes contact makes contact with something that makes contact with it. But it is possible, as we sometimes say, for the mover alone to make contact with the moved, and for what makes contact not to be made contact with by what it makes contact with (but because things of the same kind move by being moved, it seems necessary for what makes contact to be made contact with). So if something moves while being immovable, it will make contact with the thing moved, but nothing will make contact with it; for we sometimes say that a person who grieves us "touches" us, but we do not touch him.

As regards contact among natural objects, then, let it be determined in this way.

1.7
Affecting and Being Affected (1)

323b1 The next thing that must be spoken about is affecting and being affected; for the accounts we have received from earlier thinkers are contrary to each other. For most are unanimous in saying this, namely, that like is in every case unaffectable by like, since one is no more capable of affecting or of being affected than the other (for all the same [affections] belong equally to like things), while it is unlike things and different ones that naturally affect and are affected by each other; for even when a smaller fire is caused to pass away by a much greater one, it is so affected, they say, because of the contrariety; for much is contrary to little. Democritus, on the other hand, stated a view contrary to the others and special to himself alone; for he says that the affecter and the affected are the same and like; for he does not allow things that are distinct and different to be affected by each other; on the contrary, even if things that are distinct do in some way affect each other, it is not insofar as they are distinct but insofar as they have the same something that this happens to them.

The things said, then, are these. And those who speak in this way seem to appear to be saying contrary things. And the cause of their speaking in contrary ways is that while it is necessary to get a theoretical grasp on the whole, each side succeeds in stating [only] a part of it. For that like—that is, what is entirely and in every respect undifferentiated—is not affected in any way by like is reasonable. (For why will one be more capable of affecting than the other? And if like is affectable by like, it is also affectable by itself; and yet if things are like that, there would be nothing incapable

of passing away or immovable, if indeed like insofar as it is like is capable of affecting things; for everything will move itself.) And [that] what is entirely distinct and in no way the same [is not affected in any way] is likewise reasonable. (For whiteness could not be affected in any way by a line, or a line by whiteness, except coincidentally—for example, if the line were coincidentally white or black; for things that are neither contraries nor composed of contraries could not displace each other[19] from their own nature.)

But since no random thing is naturally disposed to be affected and to affect, but rather things that have a contrariety or are contraries, it is necessary for the affecter and the affected to be like—in fact, the same—in kind, but unlike and contrary in form; for it is natural for a body to be affected by a body, flavor by flavor, color by color, and, in general, what is the same in kind by what is the same in kind. The **324^{a}1** cause of this is that all contraries are in the same kind, and it is contraries that affect and are affected by each other. So it is necessary for the affecter and the affected to be in one way the same, and in another way distinct and unlike each other. And since the affected and the affecter are the same and alike in kind, but unlike in form, and contraries are things of this sort, it is evident that contraries and intermediates are affectable by and capable of affecting each other; for it is, in general, in these that passing away and coming to be reside.

That is why it is reasonable too for fire to heat and for cold to cool, and why, in general, the thing capable of affecting makes the affected one like itself; for the affecter and the affected are contraries and coming to be is to the contrary thing. So it is necessary for the affected to change to the affecter; for this is the way coming to be will be to the contrary thing. And it is also in accord with reason, then, that both sides, though not saying the same things, touched on the nature [of the phenomenon] in a similar way. For sometimes we say that the underlying subject is affected (for example, we say that a human being comes to be cured, heated, and cooled, and other things in the same way), but sometimes we say that what is cold comes to be heated and what is ill cured. And both are true. It is the same way in the case of the affecter; for sometimes we say that a human being heats, and sometimes that what is hot does; for there is a way in which matter is affected, and a way in which the contrary is. Those, then, who looked to the former thought that the affecter and the affected must possess the same something, while the others looked to the latter and thought the contrary.

The same account must be assumed to apply to affecting and being affected, just as to being moved and moving; for something is also said to be a mover in two ways; for that in which the starting-point of movement is present seems to move things (for the starting-point is primary among the causes), and again the last in relation to the moved and the [thing's] coming to be. Likewise with affecter; for we also say both that a doctor cures and that wine does. In the case of movement nothing prevents

19. Reading ἄλληλα.

the first mover from being immovable; in some cases this is even necessary; but the last is always a moved mover. And in the case of affection, while the first [affecter] is unaffectable, the last is also itself affected; for things that do not have the same matter affect while being unaffectable, for example, the craft of medicine; for this produces health but is not at all affected by what is being cured, while the food affects and is itself somehow affected; for it is heated, cooled, or affected in some other way at the same time as it affects. The craft of medicine, indeed, serves as starting-point, while the food serves as the last thing and the one making contact. So things capable of affecting that do not have their shape [or form] in matter are unaffectable, while those that do have it in matter are affectable. For the matter, we say, is alike—(one might almost say) is the same—for either of the two opposites, being, as it were, the kind, and something capable of being hot is necessarily heated if what is capable of heating is present and comes near. That is why, as has just been said, some things capable of affecting are unaffectable while others are affectable. And it is the same way in the case of things capable of affecting as in the case of movement; for there the first mover is unmoved, and in the case of the affecters, the first is unaffectable.

But the affecter is a cause as the starting-point from which the movement comes, while the for-the-sake-of-which is not capable of affecting. That is why health is not capable of affecting, except by metaphorical transference; for when in fact the affecter is present what is affected comes to be something, but when states are present it is not any longer becoming something, but already *is*, and forms and ends are certain states, while matter, insofar as it is matter, is affectable. To be sure, fire has the hot in its matter. But if hot were to exist separated, it would not be affected at all. It is perhaps impossible for this to be separated, but if there were such things, what was said would be true of them.

Let, then, what affecting and being affected is, to what things they belong, and why and how, be determined in this way.

1.8
Affecting and Being Affected (2)

But let us speak again about how it is possible for this to happen. It seems to some people that each thing is affected when the last affecter—the affecter in the strictest way—enters in through some sort of "pores," and they say that it is in this way that we see and hear, and that all the other perceptual modalities perceive things. Further, they say that things are seen through air, water, and transparent bodies because they have ducts, invisible because of their smallness, but densely aligned in columns, and the more transparent the body, the more it has.

Some people, then, determined certain cases in this way, just as Empedocles also did—not only cases of affecting and being affected, but also mixing, which they say occurs between bodies whose ducts match each other. Leucippus and Democritus,

however, made the most methodical determinations about all [these] things, having **325ª1**
made a starting-point that is in accord with nature, precisely as nature is. For some of
the ancient philosophers believed that being is of necessity one and immovable; for
the void is a non-being, and moving would be impossible if there is not a separated
void; nor, again, would there be many things if there is nothing dividing them. And 5
to this point it makes no difference whether someone thinks that the totality is not
continuous, but making contact while being divided, rather than claiming that there
are many things, not one, and a void. For if it is divisible at every contact point,
there is no one, so that there is no many either, but rather the whole is a void. But if
it is divisible at one point but not at another, it has come to seem like some sort of
fabrication; for up to what quantity, and why, is one part of the whole this way—that 10
is, a plenum—and another part divided? Further, it is equally necessary [on this view]
for there not to be movement. On the basis of these arguments, then, overstepping
and disregarding perception, on the supposition that they must follow reason, they
say that the totality is one and immovable, and some that it is unlimited; for the limit
would be a limit next to the void. These people, then, in this way and due to these 15
causes proclaimed their "truth."

But since in view of the arguments these things do seem to follow, but in view of
the facts to believe them without more ado is much the same as mania (for no one suf-
fering a manic attack degenerates to the extent of believing that fire and ice are one;
rather, it is only beautiful things and those that appear so because of intimacy, that
to some, because of their mania, seem not to differ); Leucippus, for his part, thought
he had accounts that, saying things in agreement with perception, did not do away
either with coming to be and passing away or movement or with the plurality of the
beings. Having agreed on these points with the things that appear to be so, and with 25
those that establish the one in supposing that there would be no movement without
a void, that the void is a non-being, and that no part of being is a non-being, he says
that being, in the strictest sense,[20] is being that is a total plenum, but that what is like
this is not one, but unlimited in number, and invisible because of the smallness of the
masses. These things spatially move in the void (for there is void), and their coming 30
together produces coming to be, their dissolution passing away. And they affect and
are affected to the extent that they happen to be in contact (for, in that respect, they
are not one), and when they are put together and interwoven there is coming to be.
From what is truly one, on the other hand, a multiplicity could not have come to
be, nor from what is truly many could one have; on the contrary, this is impossible. 35
However, just as Empedocles and some of the others say that things are affected
through ducts, so Leucippus says that all alteration and all being affected come about **325ᵇ1**
in this way: dissolution and passing away because of the void, and likewise growth,
by other things slipping in.

20. Reading κυρίως ὄν.

For Empedocles too it is pretty much necessary to speak just as Leucippus also does; for he must say that there are certain solids, which, however, are indivisible, unless there are continuous ducts at every point. But this is impossible; for then there will be nothing solid besides the ducts, but all of it will be void. It is necessary, therefore, for things that are making contact to be indivisible, while the intermediates between them are voids, and these he says are *poroi*. This is the way Leucippus too speaks about affecting and being affected.

These, then, are pretty much the ways these [atomists] spoke about some things affecting and others being affected. And where they are concerned, it is clear what they say, and it is evident that it follows pretty much in agreement with the assumptions they employ. With the others, it is less so—for example, in the case of Empedocles it is not clear in what way there will be passing away and alteration. For to the others the primary bodies are indivisible, differing only in figure—from which primary ones [the other things] are composed and into which, as ultimate ones, they are dissolved. In the case of Empedocles, by contrast, it is clear that the other things have coming to be and passing away down to the elements, but about these elements themselves, heaping up a magnitude, it is neither clear how they come to be and pass away nor is it possible for him to tell us, unless he says that there is an element of fire as well, and likewise of all the others, as Plato wrote in the *Timaeus*.

For the latter is to this extent different from the way stated by Leucippus, namely, that while he says that the indivisibles are solids, Plato says that they are planes, and that while for him each of the indivisible solids is determined by [one of] an unlimited number of figures, for Plato they are limited, while both say that they are indivisible and are determined by figures.[21] From these indivisibles, then, we get comings to be and disaggregations. But for Leucippus there would be two ways, because of the void and because of contact (for it is with respect to this that each is divided), while for Plato it is by contact only; for he says that there is no void.[22]

We have also spoken about the indivisible planes in previous accounts.[23] As regards the indivisible solids, although getting a full theoretical grasp on what follows from them is something we must put aside for the moment, by way of a short digression we may say that it is necessary for each of the indivisibles to be unaffectable (for it is not possible to be affected except because of the void) and incapable of producing any affection [in anything else]; for it cannot be either cold or hard. And yet this, at any rate, is impossible, to assign hot only to the spherical figure; for then it is necessary for its contrary, cold, to belong to some other figure. And it would also be absurd to suppose if they possess these—I mean hot and cold—that they will not possess heaviness and lightness and hardness and softness. And yet Democritus says that each of the indivisibles is heavier, at any rate, in accord with the excess [of size], so that it

21. *Ti.* 52d–57d.
22. *Ti.* 58a.
23. *Cael.* 298ᵇ33–300ᵃ19, 306ᵃ1–306ᵇ2.

is clear that it is also hotter [in accord with the excess of size]. But if they are like this, it is impossible for them not to be affected by each other—for example, the slightly cold by the far exceeding hot. Moreover, if hard and soft [belong], well, something is said to be soft because it is affected by something; for what is capable of being pressed in is soft.

Moreover, it is absurd both if nothing belongs to them except shape alone, and, if something does belong, for it to be one thing only—for example, hard in one case, hot in another; for then there would not be some one nature belonging to these things. It is equally impossible too if several belong to one; for since it is indivisible, it has its affections in the same place. So that if it is affected, where it is[, for example,] cooled,[24] there it will affect or be affected in some other way as well. And it is the same way in the case of the other affections; for this consequence will follow in the same way both for those who say that the indivisibles are solids and for those who say that they are planes; for they cannot come to be either rarer or denser, because there is no void within the indivisibles.

Further, it is absurd too for small things to be indivisible, but not large ones; for as things stand it is reasonable for large ones to break up rather than small ones; for the former—namely, the large ones—more easily come apart, since they collide with many things. But why should indivisibility in general belong to small things rather than to large ones?

Further, is there one nature for all these solids, or do some differ from others, as would be so if some were fiery in their mass, others earthen? For if there is one nature for all, what separates them? Or else why, when they make contact, do they not become one, as a raindrop does when it makes contact with a raindrop? For the one behind is no different from the one in front. On the other hand, if they are distinct, of what sorts are they? And it is clear that these must be posited as starting-points and causes of the things resulting from them, rather than the shapes.

Further, if they were different in nature, they would both affect and be affected on **326**^{b}**1** making contact with each other.

Further, what is their mover? For if it is a distinct thing, they will be affectable. On the other hand, if each moves itself, either it will be divisible (with respect to one part a mover, with respect to another a moved) or contraries will belong to it with respect to the same part, and its matter will be not only one in number but also potentially.

As for those who say that affections come about because of movement through ducts, even if the ducts are total plenums, the ducts are superfluous; for if this is how the totality is affected in some way, even if it had no ducts but were itself continuous, it would be affected in the same way.

Further, how is it possible for seeing through a medium to happen in the way they say?[25] For it is not possible to pass through the transparent medium either at the

24. Reading ἢπερ ψύχεται.
25. Empedocles B84 DK (= *Sens.* 437^{b}26–438^{a}2), Plato, *Timaeus* 45b–46c.

points of contact or through the ducts, if each of these ducts is a plenum. How will it differ, then, from what does not have ducts? For all of it will be similarly plenums. But even if these ducts are voids, though it is necessary for them to have [other] bodies in them, the same thing will again result. And if they are of such a magnitude as to receive no body, it is ridiculous to think that what is small is a void, but not what is large, whatever its size—that is, to think that "void" means something other than "space for body," so that it is clear that for every body there will be a void of equal mass.

In general, then, to posit ducts is superfluous; for if nothing can affect anything by making contact with it, neither will it affect it by passing through its ducts. On the other hand, if it can do so by making contact, then—even if there are no ducts—some things will be affected and others will affect them, provided they are naturally adapted in this way to each other.

That speaking in this way about ducts, as some have supposed they must, is either false or pointless, is evident from these considerations; for if bodies are divisible at every point, it is ridiculous to posit ducts; for where they are divisible, they are capable of being separated.

1.9
Affecting and Being Affected (3): Potentially versus Actually

In what way being a cause of coming to be [such-and-such] and affecting and being affected belong to the beings, we state by taking for granted an often-mentioned starting-point; for if, on the one hand, there is what is potentially such-and-such and, on the other hand, what is actually such-and-such, it is natural for [what is affected] to be affected not at one point and not at another, but rather at all points, to the extent that it is such-and-such, though to a lesser or greater extent insofar as it is more or less such-and-such. And one would more properly speak about ducts in this connection as veins of affectability, just like [veins of ores] stretching continuously in mines.

327ᵃ1 Certainly, when grown together and one, each thing is unaffectable. Likewise too when things are making contact neither with each other nor with other things that are naturally affecting and affected. I mean, for example, that fire heats not only when making contact with things but also when at a distance from them; for the fire heats the air, and the air—being naturally affecting and affected—heats the body.

As for thinking that a thing is affected in some part but not in another, having drawn distinctions at the start,[26] this is what must be said. For if a magnitude is not divisible at every point, but there is a body or a plane that is indivisible, it would not be affectable at every point, but neither would any magnitude be continuous. On the

26. 316ᵃ14–317ᵃ17.

other hand, if this is false and all body is divisible, it makes no difference whether it was divided and is making contact or it is divisible; for if it is capable of being disaggregated at the contact points, as some people say, even if it is not yet divided, it will be divided; for it is possible for it to be divided; for nothing impossible results.

In general, it is absurd for it to be only in this way, namely, by bodies being split, that anything comes to be [such-and-such]; for this account does away with alteration, while we see that the same body, while being continuous, is at one time liquid and at another time solidified, and being affected in this way not due to division and composition, or "turning" and "making contact," as Democritus says; for it has become solid from liquid without any change of order or position in its nature, nor does it now have hard and solidified particles, indivisible in mass—on the contrary, in the same way as it was liquid throughout, it is now hard and solidified throughout.

Further, neither is it possible for there to be growth and withering; for not every part whatever will have become larger, if indeed [the change happening] is addition, and the totality will not have changed either by mixing with something or by having changed intrinsically.

One must determine in this way, then, that there is a cause of coming to be [such-and-such] and affecting, coming to be [such-and-such] and being affected by each other, and in what way they are possible, and in what way some say they are, although it is not a possible one.

1.10
Mixing

It remains to get a theoretical grasp on mixing in accord with the same mode of methodical inquiry; for this was the third of the things we proposed at the start.[27] We must investigate what mixing is, what it is to be mixable, and to which sort of beings it belongs, and in what way, and further, whether mixing exists, or whether this is false; for some people say that it is impossible for one thing to be mixed with another; for if the things that have been mixed still exist and have not been altered, they are no more mixed now, they say, than previously, but are in a similar state; but **$327^{b}1$** if one of the two has passed away, they have not been mixed, but one exists and the other does not, while mixing is of two things in a similar state; and it is the same way even if when both of the things have come together, each of the things being mixed passes away; for things that have no being at all are not mixed. This argument, then, seems to be seeking to determine in what respect mixing differs from coming to be and passing away, and in what respect what is mixable differs from what can come to be and pass away; for clearly it must differ, if indeed it exists. So once these things are evident, the puzzles would be resolved.

27. $322^{b}25–26$.

We do not say that wood has been mixed with fire, nor that it is being mixed when it burns, either itself with its very own parts or with the fire. On the contrary, we say that the fire comes to be and that the wood passes away. In the same way, we do not say that nourishment is mixed with the body, or that the shape is mixed with the wax when it shapes its mass. Nor can the body and white—nor, in general, affections and states—be mixed in the things that have them; for they are seen to be preserved. But then neither can white and scientific knowledge be mixed, nor any other of the non-separables. Indeed this is what those who say[28] that everything at one time was together and mixed say incorrectly; for not everything is mixable with everything; on the contrary, each of the things that have been mixed must preexist separately; but no affection is separable.

But since some beings are potentially and others actually, it is possible for things that have been mixed in a certain way to be and not be, with what comes to be from them actually being distinct, and each of the very things that existed before being mixed still potentially being, and not having passed away; for this is the puzzle that the previous argument raised, and it is evident that things that are mixed come together from having been previously separate, and are capable of being separated again. So they neither actually remain, like the body and white, nor do they—either or both—pass away; for their capacity [or potential] is preserved. That is why this [puzzle] may be set aside.

However, a puzzle connected to this must be analyzed, as to whether mixing is something relative to perception. For when the things that are mixed have been divided up so small and have been put next to each other in such a way that each is not clear to perception, have they, then, been mixed, or is it not so, but rather that any part whatever of one is next to some part of the other? It is in the first way that it is said, for example, that grains of barley are mixed with grains of wheat, when any grain whatever of one is put next to some grain of the other. But if all body is divisible, if indeed a body that can be mixed with another is uniform, any part whatever of one must come to be next to some part of the other.

But since it is impossible for a body to be divisible into smallest particles, and since composition is not the same as mixing but distinct from it, it is clear that one must not say *either* that the things are mixed, if they are preserved at the level of small particles—for this will be composition and not blending or mixing, nor will the part have the same account as the whole, while we say that, if indeed they have been mixed, the mixture is uniform, and that just as a part of water is water, so it is too for what has been blended; however, if mixing were just composition at the level of small particles, none of these things will follow, but there will only be things that are mixed relative to perception, and the same thing will be mixed to one person whose sight is not sharp, while to Lynceus nothing will be mixed—*or*, if they are so divided, that

28. E.g., Anaxagoras.

any part whatever [of one] is next to some part [of the other], for it is impossible for them to be divided in this way.

Either mixing does not exist, then, or it is necessary to state once again in what way it can possibly come about. There certainly are, we say, some beings that are capable of affecting and others affectable by them. Moreover, some—namely, those that have the same matter—convert, that is, are capable of affecting each other and of being affected by each other. Other things, by contrast, though they affect, are unaffectable, namely, those that do not have the same matter. Of these, then, there is no mixing. That is why neither the craft of medicine nor health produces health by mixing with bodies.

But among things that are capable of affecting and of being affected and are easy to divide, when many of these are put together with few, or large with small, this does not produce mixing, but rather growth of the mastering one; for the other changes into the mastering one, which is why a drop of wine does not mix with ten thousand *choes* of water; for its form dissolves and changes to the totality of the water. But when the two are more or less equalized in capacity, then each of them changes from its own nature toward the mastering one, although it does not become the other, but something intermediate and common. It is evident, then, that the mixable are the affecters that have a contrariety; for it is these indeed that are affectable by each other.

Also, small particles put next to small ones are more mixable; for these more easily and more quickly change each other, while a large one, even under the influence of a large one, takes much time to accomplish this. That is why, of the things that are divisible and affectable, the easily bounded ones are mixable (for they divide easily into small particles; for this is what it is to be easily bounded). For example, the liquids are the most mixable of the bodies; for of the divisible things, what is liquid is most easily bounded, provided it is not viscous; for viscous ones, it is true, merely make the mass greater in volume and larger.

But when only one of the two [things being mixed] is affectable—or is extremely so, while the other is altogether slightly so—the mixture of both is either not at all, or [only] a little, greater [in volume]—which is precisely what happens with tin and bronze. For some of the beings are hesitant with each other and play a double game; for they appear in a way as both slightly mixed and in a way as one of the two being recipient and the other form. And this is precisely what happens in the case of these; for the tin, like some affection of the bronze that is without matter [of its own], pretty much vanishes after being all mixed, giving its color only. And the same thing happens in other cases.

It is evident, therefore, from what has been said that mixing exists, what it is, and what causes it, and also what sorts of beings are mixable, since indeed they are the sorts of things that are affectable by each other, easily bounded, and easily divided; for it is neither necessary for these to pass away having been mixed, nor for them to be unconditionally still the same, nor for the mixing of them to be composition, nor to be in relation to perception. On the contrary, something is mixable that is easily

bounded, and is capable of being affected and of affecting, and is mixable with a thing that is of this sort (for what is mixable is so in relation to a homonym), and mixing is the unification of mixable things when they have been altered.

BOOK 2

2.1
The Elements of Bodies (Earth, Water, Air, Fire) and Their Matter

We have spoken about what way mixing, contact, affecting, and being affected belong to things that in accord with nature are subject to change, and further, about unconditional coming to be and passing away, in what way they happen, and to what, and due to what cause. Similarly, we have spoken about alteration, what alteration is, and how it differs from these. It remains to get a theoretical grasp on the so-called elements of bodies. For coming to be and passing away in the case of all substances that are by nature composite do not occur without the perceptible bodies.

Of these, the underlying matter is said by some people to be one, supposing it to be air or fire or something intermediate between these that is a body and separable. But **329ᵃ1** others say that it is more than one, some saying fire and earth, others these and air as a third, others these and water as a fourth, as Empedocles did. From the aggregation and disaggregation or alteration of these, the coming to be and passing away in things result.

Let it be agreed that the primary things are correctly said to be starting-points and elements, the ones from whose changing, whether by aggregation and disaggregation or another [sort of] change, coming to be and passing away result. But those, on the one hand, who posit a single matter beyond these, and it corporeal and separable, are making an error; for it is impossible for this perceptible body to exist without a contrariety; for it is necessary for this unlimited, which some say[29] is the starting-point, to be either light or heavy or cold or hot.

And the way things are written in the *Timaeus*[30] has nothing definite about it; for [Plato] does not state perspicuously whether the all-receptive is separated from the elements, nor does he make any use of it when he says that it is a sort of underlying subject that is prior to the so-called elements, as gold is to works in gold (and yet this, said in this way, is not stated correctly: for the things of which there is alteration, it is this way, but for those of which there is coming to be and passing away, it is impossible to call something that from which it has come to be, and yet he says that by far the truest thing to say is that each of them is gold); on the other hand, he takes the

29. In particular, Anaximander.
30. 50b–c, 53c–57d, 49a.

resolution of the elements, which are solids, to extend as far as to planes, though it is impossible for planes to be the "wet nurse" and the primary matter.

For our part, we say that although there is a sort of matter for the perceptible bodies, it is not separable but always goes along with a contrariety, and from this the so-called elements come to be. A more exact determination about these has been made elsewhere.[31] Nonetheless, since this is indeed the way that the primary bodies come from matter, we must make a determination about these also, thinking the matter, though inseparable, to be a primary starting-point, underlying the contraries; for neither is hot matter for cold, nor it for hot, but rather the underlying subject is matter for both. So first there is the starting-point for what is potentially a perceptible body; second, the contrarieties (I mean, for example, hot and cold); and only then, third, fire, water, and things of that sort; for these do change into each other, and it is not the way Empedocles and others say (for then there would be no alteration), while **$329^{b}1$** the contrarieties do not change. But nonetheless, even so we must state what sort and how many of them are the starting-points of body; for the others assume and make use of them, but say nothing about why they are these or this many.

2.2
The Primary Contrarieties: Hot and Cold, Dry and Wet

Since what we are seeking are the starting-points of perceptible body, that is, of tangible body, and a tangible body is that for which touch is the perceptual modality, it is evident that not all contrarieties produce forms and starting points of body, but only those in accord with touch; for it is in accord with a contrariety that they differ, and [specifically] in accord with a tangible contrariety. That is why neither whiteness and blackness, sweetness and bitterness, nor (similarly) any of the other perceptible contrarieties [besides the tangible ones] produces an element. And yet sight is prior to touch, so that its subject matter too is prior; but it is not an affection of tangible body insofar as it is tangible, but rather is in accord with something else, even if it happens to be prior in nature. It is among the tangible affections themselves, then, that one must distinguish which ones are primary differences and contrarieties.

The contrarieties that are in accord with touch are these: hot cold, dry wet, heavy light, hard soft, viscous brittle, rough smooth, coarse-grained fine-grained. Of these, heavy and light are neither capable of affecting nor of being affected; for they are not said of things in virtue of their affecting something else or being affected by something else. The elements, though, must be capable of affecting and being affected by each other; for they mix and change into each other. Hot and cold, by contrast, and wet and dry are said of things, the one lot being capable of affecting, the other capable of being affected; for hot is what aggregates things of the same kind (for the

31. *Ph.* 1.6–9, *Cael.* 3–4.

disaggregating, which is precisely what they say fire does, is the aggregating of things of the same kind; for this results in removing what is alien) and cold is what brings together and aggregates alike things of the same kind and things not of the same kind. Wet is what is not bounded by any defining mark proper to it, though it is easily bounded [by other things]; dry is what is easily bounded by a defining mark proper to it, though difficult [for other things] to bound.

And the fine-grained and coarse-grained, viscous and brittle, hard and soft, and the other differences are derived from these; for since being capable of filling things belongs to the wet, because it does not have boundaries but is easily bounded, and follows along with what it makes contact with, and the fine-grained is capable of filling things (for its particles are fine, and what has small particles is capable of filling things; for whole makes contact with whole; and the fine-grained is most of all like this), it is evident that the fine-grained belongs to the wet, while the coarse-grained belongs to the dry. Again, the viscous belongs to the wet (because the viscous is the wet affected in some way, like olive oil), while the brittle belongs to the dry; for the completely dry is brittle—so that it has been solidified because of lack of liquid. Further, the soft belongs to the wet (for what can be pressed into itself and does not move to another place, which is precisely what the wet does, is soft; that is why it is also the case that the wet is not soft, but the soft does belong to the wet) and the hard to the dry; for what is solidified is hard and what is solidified is dry.

Things are said to be dry and wet in many ways; for both wet and moist are opposed to dry, and, in turn, both dry and solid are opposed to wet; but all these belong to the wet and the dry said in the primary way. For since dry is opposed to moist, and moist is what has alien liquid on its surface, while soaked is what has it to its depths, and dry is what is deprived of it, it is evident that moist will belong to the wet, and the dry that is opposed to it to what is dry in the primary way. Again, wet and solid are opposed in the same way; for wet is what has its own liquid down to its depths (while soaked is what has alien liquid down to its depths), and solid is what is deprived of this, so that these too belong, the one to the dry, the other to the wet.

It is clear, therefore, that all the other differences are led back to the primary four, while these can no longer be led back to fewer ones; for neither is the hot precisely wet or precisely dry, nor is the wet precisely hot or precisely cold, nor do the cold and the dry fall under each other or under the hot and the wet. So necessarily there are these four.

2.3
The Contrarieties and the Elements

Since the elements are four in number, and of the four the pairings are six, and contraries do not naturally pair (for it is impossible for the same thing to be hot and cold, or, again, wet and dry), it is evident that the pairings of the elements will be four in number: hot and dry, hot and wet; and, again, cold and wet and cold and dry.

And these follow along, in accord with reason, with the apparently simple bodies: **330^{b}1**
fire, air, water, and earth; for fire is hot and dry, air hot and wet (for air is like vapor),
water cold and wet, and earth cold and dry, so that the differences are allocated to the 5
primary bodies in a reasonable way, and the number of these is in accord with reason.

For of all those who make the simple bodies elements, some make them one, some two, some three, some four. The result for those who say that there is one only, and then generate the others by condensation and rarefaction, is to make the starting-points 10
two: the rare and the dense, or the hot and the cold; for these are what play the role of handicraftsmen, while the one underlies them as matter. Those who make them two right from the start, as Parmenides does with fire and earth, make the intermediates—for example, air and water—mixtures of these. And it is the same way too for those who 15
speak of three, as Plato does in the divisions;[32] for he makes the middle a mixture. And those who make them two and those who make them three are pretty much saying the same thing, except that the former divide the intermediate in two, while the latter make it one only. But some say there are four right from the start, as Empedocles does—but he in fact leads them back to two; for he opposes all the others to fire. 20

Fire, however, and air and each of the others that have been mentioned are not simple, but mixed. The simple ones are like these, but not the same as them—for example, if something is like fire, it is fire-form, not fire, and if like air, it is air-form, and likewise in the other cases. Fire is excess of hotness, just as ice is of coldness. 25
And solidification and boiling are excesses of a sort, the one of coldness, the other of hotness. If, then, ice is the solidification of wet and cold, fire will be the boiling of dry and hot. That is why nothing comes to be either from ice or from fire.

Since the simple bodies are four in number, two of each [pair] belong to each of 30
the two places[33] (fire and air belong to what spatially moves toward the limit, earth and water to what spatially moves toward the center). And earth and fire are the extremes and the purest, while water and air are intermediates and more mixed. And two of them are contrary to the other two, for to fire water is contrary, and to air **331^{a}1**
earth; for they are composed of the contrary affections. Nonetheless, being four in number, each is unconditionally one: earth is dry more than cold, water cold more than wet, air wet more than hot, and fire hot more than dry. 5

2.4
The Change of the Elements into Each Other

But since it has been determined previously[34] that coming to be for the simple bodies is from each other, and at the same time too it is evident from perception that they come to be (for otherwise there would be no alteration; for alteration is with respect

32. *Timaeus* 35a–37d.
33. Reading τόπων.
34. *Cael.* 3.6.

to the affections of tangible things), we must speak about what way they change into each other, and whether every one can come to be from every one or whether some can but others cannot.

That all do naturally change into each other is evident; for coming to be is to contraries and from contraries, and the elements all have a contrariety in relation to each other due to their differences being contraries; for some both differences are contraries, for example, fire and water (for the one is dry and hot, the other wet and cold), for others only one is, for example, air and water (for the one is wet and hot, the other wet and cold). So universally, then, it is evident that all naturally come to be from all, and it is not difficult to see immediately with respect to each particular one in what way this occurs; for while all will come to be from all, they will differ with respect to faster and slower and with respect to easier and more difficult. For those that have tokens in relation to each other, the change is fast, and for those that do not have them, slow, because it is easier for one thing to change than for many. For example, from fire there will be air when one of the two [differences] changes (for the former was hot and dry, while the latter is hot and wet, so that if the dry is mastered by the wet, it will be air). Again, from air there will be water, if the hot is mastered by the cold (for the former was hot and wet, while the latter is cold and wet, so that if the hot changes, it will be water). And in the same way from water earth and from earth fire; for both have tokens in relation to each other; for water is wet and cold, while earth is cold and dry, so that when the wet is mastered, it will be earth. And again since fire is dry and hot, while earth is cold and dry, if the cold passes away, there will be fire from
331b1 earth. So it is evident that the coming to be of the simple bodies will be in a circle, and this will be the easiest way of change, because there are tokens present in the successive ones.

It is possible, however, for water to come to be from fire, and from air earth, and again from water and earth for air and fire to do so, but it is more difficult, because there is change of more [affections]; for it is necessary, if there is going to be fire from water, that both the cold and the wet have passed away, and again if there is going to be air from earth, that both the cold and the dry have passed away. In the same way too if there is going to be water and earth from fire and air, it is necessary for both to change.

This sort of coming to be, then, takes more time. But if one [affection] of each of the two has changed, the change, though easier, is not into each other. On the contrary, from fire and water there will be earth and air, and from air and earth there will be fire and water. For when the cold of the water and the dry of the fire have passed away there will be air (for there remains the hot of the latter and the wet of the former). But when the hot of the fire and the wet of the water have passed away there will be earth, because of the remaining of the dry of the former and the cold of the latter. In the same way too from air and earth there will be fire or water; for when the hot of the air and the dry of the earth have passed away, there will be water

(for there remains the cold of the latter and the wet of the former). But when the wet of the air and the cold of the earth have passed away there will be fire, because of the remaining of the hot of the former and the dry of the latter, and these, as we saw,[35] are just what belong to fire. And this coming to be of fire is also in agreement with perception; for flame is most of all fire, and flame is burning smoke, and smoke is composed of air and earth.

In the case of successive bodies it is not possible for the passing away of one of the elements in each of them to have brought about a change into any of the bodies, because of the remaining in both either of the same ones or the contrary ones. And from neither of these is it possible for a body to come to be—for example, if the dry of fire passed away, and the wetness of air; for in both cases the hot remains. Or if the hot passed away from both, contraries remain, namely, dry and wet. It is the same way too in the other cases. For in all the successive ones there exists, on the one hand, the same [token] and, on the other, a contrary one. So at the same time it is clear that a change from one [body] to one [body] comes about through the passing away of one [token], while a change from two to one comes about through the passing away of more than one.

That all come about from all, and in what way their change into each other comes about, has now been stated. **332^{a}1**

2.5
Ways in Which the Elements Change into Each Other

Nonetheless let us also get a further theoretical grasp on these matters in the following way. For if the matter of natural bodies is, as it seems to some people to be, water, air, and things of that sort, it is necessary for there to be one, two, or more of these. But they cannot all be one—for example, all air, or water, or fire, or earth—if indeed change is into the contraries. For if it were air, and if it remains, [the change] will be alteration, but it was [supposed to be] coming to be. At the same time, it does not seem to anyone that [it occurs] in such a way that water is at the same time also air (or whichever of the others). There will, then, be some contrariety (that is, a difference) involved, of which something will have one of the two parts—for example, fire hotness. Nonetheless, fire will not be hot air; for something of that sort is alteration, and is not what appears to happen. And at the same time, again, if there is to be air from fire, it will be due to the changing of the hot into its contrary. Therefore, this contrary will belong to the air, and the air will be something cold. So it is impossible for fire to be hot air; for then the same thing will be hot and cold. Therefore, both air and fire will be some same distinct thing, that is, some distinct sort of matter that is common to them.

35. 330^{b}3–4.

The same argument applies to all of them, because it is not possible for there to be one of them from which all derive. But neither is there some other one beyond these—for example, a sort of intermediate between air and water or between air and fire (coarser-grained than air or fire, but finer-grained than the others); for air and fire will be that thing together with a contrariety. But one of the contraries is a privation. So it is not possible for this thing ever to be alone, as certain people say[36] the unlimited is and the encompassing. Therefore, it is indifferently any of these whatever, or none of them. If, then, nothing—at any rate, nothing perceptible—is prior to these, it would be all of these. Therefore, it is necessary either for them to always remain and not change into each other or for all of them to change, or for some to do so but not others, as Plato wrote in the *Timaeus*.[37] That it is necessary for them to change into each other was proved previously;[38] and that they do not do so equally quickly one from another was stated previously, because those that have a token come to be from each other faster, and those that do not have one, slower.

If, therefore, the contrariety with respect to which they change is one, it is necessary for there to be two [elements]; for the matter is the intermediate thing, being imperceptible and inseparable. But since there are seen to be more [elements], two would be the smallest number. And if there are two [contrarieties], there cannot be three [elements], but rather four, as is evident; for this is the number of pairings; for of the six, two cannot have come about because of being contraries to each other.

These matters have been spoken about previously.[39] But, since they change into each other, that it is impossible for there to be a starting-point of them either at the extremity or the middle will be clear from the following. In the case of the extremes, it will not be possible, because all will then be fire or earth, and the account is the same as the one saying that all come from fire or earth. Nor is it possible that it is an intermediate, in the way that it seems to some[40] that, while air changes both into fire and into water, and water both into air and into earth, the extremes do not any longer change into each other; for the process must come to a stop and not go on without limit in a straight line in either direction. For then there will be an unlimited number of contrarieties in the case of one [element].

Let E stand for earth, W for water, A for air, and F for fire. If, then, A changes to F and W, there will be a contrariety belonging to AF. Let these contraries be whiteness and blackness. Again, if A changes to W, there will be another contrariety (for W and F are not the same thing). Let these contraries be dryness and wetness: D for dryness, W for wetness. But if white remains, wet and white will belong to water; if it does not, water will be black; for change is to the contrary. Therefore, it is necessary for water to be either black or white. Let it be the first. On similar grounds, therefore,

36. E.g., Anaximander.
37. 54b–d.
38. 331a12–332a2.
39. 2.2–3.
40. Reference unclear.

D (dryness) will belong to F. Therefore, there will also be a change of F (fire) into water; for contraries belong to them; for fire was first taken to be black, then dry, water wet, then white. It is evident, then, that there will be change from each other in every case, and, in the cases taken, that E (earth) will have the remaining two tokens, black and wet; for these have not yet been paired.

And that it is not possible to proceed without limit—which is precisely what we were going to prove, but we dealt with this issue before it—is clear from the following. For if in turn fire (which F stands for) changes into something else, into X for example, and does not turn back, there will be some contrariety belonging to F (fire) and X other than the ones just mentioned; for it has been assumed that X is the same as none of E, W, A, or F. Let K, then, belong to F, and Y to X. Then K will belong to all of E, W, A, and F, since they change into each other. But though in fact this has not yet been proved, at least it is clear that if in turn X changes into something else, another contrariety will belong to both X and F (fire). And similarly, it is always the case that along with each additional [element] some [new] contrariety will belong to the previous ones, so that if it goes on without limit, the contrarieties that belong to a single [element] will also be unlimited.

But if this is so, there will neither be a definition nor a coming to be of any [element]; for if one is to have come to be from another, it will have to go through so-and-so many contrarieties, and still more. So there will be some things into which there will never be change—namely, if the intermediates are unlimited in number (which is necessary if indeed the elements are unlimited in number). Further, there will not even be a change from water to fire, if the contrarieties are unlimited in number. Further, all will come to be one; for it is necessary for all the contrarieties of those [elements] above F to belong to those below, and of those below F to those above, so that all will be one.

2.6
Against Empedocles

One might well wonder at those who say that the elements of bodies are more than one—so that they do not change into each other, as Empedocles says—as to how it is open to them to say that the elements are comparable. And yet Empedocles does speak in this way: "For all these are equal."[41] But if it is with respect to quantity, it is necessary for there to be some same thing belonging to all the comparable elements by which they are measured—for example, from one *cotyle* of water, ten *cotyles* of air might come. Therefore, there was some one thing that both are, if they are measured by the same thing. But if they are not in this way comparable in quantity, as quantity coming from quantity, but in capacity (for example, if a *cotyle* of water had the

41. B17.27 DK.

same capacity to cool as ten of air), in this way they are comparable in quantity, not insofar as it is quantity, but insofar as it has a certain capacity. And it would indeed be possible for these capacities to be compared not by a measure of quantity, but by analogy—for example, as this is white, that is hot. However, in quality the "as this" signifies likeness, but in quantity[42] it signifies equality. It appears absurd, then, if bodies that are not capable of changing into each other are comparable not by analogy, but by a measure of their capacities, that is, that so-and-so much fire and many times that quantity of air be equal or similar in hotness; for the same thing in greater quantity, by being of the same kind, will have a ratio of this sort.

But then there would not be growth either, according to Empedocles, except by addition; for fire will grow by fire, "earth makes its own kind grow; *aithêr* makes *aithêr* grow."[43] These are additions. But it seems that growing things do not grow in this way.

It is much more difficult [for him] to give an account of the coming to be that is in accord with nature. For all the things that come to be by nature come to be either always or for the most part, while those that do so in a different way from always or for the most part come to be by chance or by luck. What then is the cause of a human always or for the most part coming to be from a human, or wheat—and not an olive tree—from wheat? Or, again, if something is put together *this* way, [why] is it bone? For when things come together by luck nothing comes to be, according to what he himself says, but only when they do so in a certain ratio. What, then, is the cause of this? For it certainly is not fire or earth. But then it is not love and strife either; for the former is the cause of aggregation only, the latter of disaggregation. In fact, it is the substance of each, not just "mixing and separation of what is mixed," as Empedocles says.[44] And "luck" is "the name bestowed on them"[45] and not "ratio"; for things can be mixed by luck. The cause, then, of things that are by nature is their being in a certain condition, and this is the nature of each, about which he says nothing. Therefore, he says nothing about nature. Moreover, this cause is the well-being and good, while he gives the praise to mixing alone. Yet the elements, at any rate, are disaggregated not by strife but by love, and are by nature prior to the god—although they too are gods.

Further, he speaks about movement in too simple a way; for it is not enough to say that love and strife move things, unless this was the being for love, namely, to move things in *this* way, while for strife it was to move them in *that* way. He should, then, either have defined, assumed, or demonstrated, either in an exact way, in a looser one, or in some other way. Further, since it is evident that the bodies move both by force—that is, contrary to nature—and in accord with nature (for example, while fire moves upward not by force, it moves downward by force), and what is by force is contrary to what is in accord with nature, and there is movement by force, there is also movement in accord with nature. Is this, then, the movement that love moves

42. Reading ἐν μὲν ποιῷ.
43. B37 DK.
44. B8.3 DK (= *Met.* 1015a2).
45. Empedocles DK B8.4 (= Aristotle, *Met.* 1015a2a).

things with? Or not? For on the contrary the movement moving the earth downward is like disaggregation, and it is strife that is the cause of this movement in accord with nature rather than love. So, in general too, love would seem to be rather contrary to nature. But unless either love or strife moves them, there is simply no movement of the bodies themselves, nor is there rest. But that is absurd.

Further, it is evident that bodies do move. [Let it be,] then, that strife disaggregated them; *aithêr*, however, was spatially moved upward, not by strife but, so he **334^{a}1** sometimes says, as if by luck: "it happened to run in this way then, but often in another way,"[46] while at other times he says that it is in the nature of fire to spatially move upward, while *aithêr*, he says, "sank under the earth with long roots."[47]

At the same time, he also says that the cosmos is in the same state now under strife as it was previously under love. What, then, was the primary mover and cause of movement? For it cannot then be love and strife. But of which of these movements are these the causes, if the primary mover is the starting-point?

It is also absurd if the soul is composed of the elements, or is one of them; for how will the alterations characteristic of the soul—such as being musical and then again unmusical, or memory or forgetting—take place? For it is clear that if the soul is fire, the affections it will have will be those of fire insofar as it is fire, and if it is a mixture, the corporeal ones. But none of these alterations of the soul is corporeal. But discussing these issues is work for another theoretical investigation.

2.7
How the Simple Bodies Mix to Form Compound Ones

As for the elements of which the bodies are composed: for those people who think that these elements have something in common or change into each other, if one of these views holds, the other necessarily follows. For those, on the other hand, who do not make the elements come to be from each other, nor in such a way as to come from each (except as bricks come to be from a wall), it will be absurd how fleshes and bones, or anything else of this sort, will come from them. And what was said also involves a puzzle for those who make the elements come to be from each other, as to what way something else beyond them comes to be from them. I mean, for example, that water comes to be from fire and fire from it, for they have something in common, namely, the underlying subject. But, of course, flesh and marrow also come to be from them. In what way, then, do these come to be?

And for those who speak as Empedocles does, what will the way be? Necessarily, in fact, it is composition, just the way a wall comes to be from bricks and stones. And this mixture will come from the elements that are preserved but put together next to each

46. B53 DK (= *Ph.* $196^{a}22$–23).
47. B54 DK.

other in the form of small particles. This, then, will be the way it is with flesh and each of the others. It follows, then, that it is not from any particle of flesh whatever that fire and water will come to be—in the way that from *this* bit of wax a sphere might come to be, and from some other bit a pyramid, but it would also be possible the other way around. This, then, is the way coming to be occurs when from any particle of flesh whatever both fire and water come to be. But for those who speak in the way under discussion it is not possible; on the contrary, it occurs in the way that from a wall a **334b1** stone and a brick come to be, one from one place and part, and another from another.

Similarly, a certain puzzle is also involved for those who posit a single matter [for the elements], as to how something is to come from two of them—for example, from hot and cold or fire and earth. For if flesh comes from both and is neither, nor again is it a composite in which they are preserved, what remains except for the matter to be what comes to be from both? For the passing away of one produces either the other or the matter. Or, since more and less applies to hot and cold, is it that when one of the two is fully actual, the other will be potential, but when it is not fully so, but in the way it is hot, it is [somewhat] cold, or [in the way it is] cold [it is somewhat] hot, because when mixed they destroy each other's excesses, at that time neither the matter nor either of the contraries will be fully actual, but rather something intermediate, which, insofar as it is more potentially hot than cold, or the contrary, is in accord with the relevant ratio potentially twice as hot as cold, or three times, or related in some other such way? The other things, then, will result from the contraries having been mixed, or rather from the elements, and the elements from the contraries, which in a certain way potentially are, not in the way the matter is, but in the way just mentioned. And in this way what comes to be is a mixture, while in the other way it is matter.

But since the contraries are also affected in the way determined in our first investigations[48] (for the actually hot is potentially cold and the actually cold is potentially hot, so that unless they are equal, they change into each other, and similarly in the case of the other contraries), in fact it is in this way that first the elements change [into each other]. And from these come flesh, bones, and things of this sort, the hot becoming cold, and the cold hot, when they approach the mean (for there they are neither), and the mean is of considerable extent and not indivisible. In the same way dry, wet, and things of this sort, in the region of the mean, produce flesh, bone, and the others.

2.8
Each Element Is Present in Every Compound

All the mixed bodies, the ones around the place at the center, are composed of all the simple bodies. For earth is present in all of them, because each simple body is most of all and in greatest quantity in its proper place. And water is, because the composite

48. 1.7.

must be bounded, and water alone of the simple bodies is easily bounded, and further, because earth is incapable of holding together without the wet, this being what keeps it together; for if the wet were completely removed from it, it would fall apart. It is due to these causes, then, that earth and water are present in them, but also fire and air, because they are the contraries of earth and water; for earth is contrary to air, and water to fire, to the extent that substance admits of being contrary to substance. Since, then, comings to be are from contraries, and one of the two [pairs of] extreme contraries is present, it is necessary for the other one to be present too, so that all the simple bodies are present in every composite one.

The nourishment of each thing seems to attest to this; for everything is nourished by the very same things it is composed of, and everything is nourished by several things. For even precisely the things that might seem to be nourished by only one thing, like plants by water, are in fact nourished by several; for earth is mixed with the water; that is why farmers try to mix in something when watering.

But since nourishment belongs with the matter, while what is nourished is the shape (that is, the form) taken together with the matter, it is immediately reasonable that fire alone of the simple bodies is nourished (though all of them come to be from each other), as previous thinkers also say;[49] for fire alone and most of all belongs with form because its nature is to spatially move toward the defining mark. And each thing naturally spatially moves toward its own place. And the shape and form of all things lie in their defining marks.

It has been stated, then, that all the [mixed] bodies are composed of all the simple bodies.

2.9
Material, Formal, and Final Causes of Coming to Be and Passing Away

But since there are some things that come to be and pass away, and coming to be does occur in the place around the center, we must state about all coming to be alike how many starting-points there are of it and what they are; for this way we will more easily get a theoretical grasp on the particular ones, namely, when we first get hold of the universal ones.

The starting-points are equal in number and [the same] in kind to those in the province of the eternal and the primary things; for one is so as matter, the other as form. But in addition, the third starting-point must also exist; for the two are not sufficient for coming to be, any more than in the case of the primary things.

49. E.g., Heraclitus and Hippasus.

The cause as matter for things that come to be is what is capable of being and of not being; for some things of necessity are (for example, the eternal ones), while others of necessity are not—of these, it is impossible for the first lot not to be, and impossible for the second lot to be, because it is not open to them, contrary to necessity, to be otherwise. Some things, however, are capable of being and of not being—which is precisely what the capable of coming to be and of passing away is; for it at one time is and at another is not. So it is necessary for coming to be and passing away to have to do with what is capable of being and of not being. That is also why this is the cause as matter for the things that come to be. The cause as the for-the-sake-of-which is the shape—that is, the form—and this is the account of the substance of each thing.

But one must also add a third, which all [philosophers] dream about, but none has stated. On the contrary, some thought that the nature of the Forms was sufficient cause for coming to be, as Socrates says in the *Phaedo*;[50] for he, in fact, after blaming others for having said nothing, supposes that some of the beings are Forms, others things that participate in the Forms, and that everything is said to be in accord with the Form, and to come to be in accord with partaking of it and to pass away in accord with losing it, so that if these things are true, the Forms, he thinks, are of necessity the causes of both coming to be and passing away. Others,[51] however, thought it was the matter itself; for[, in their view,] it is from this that the movement comes. But neither lot speaks correctly. For if the Forms are causes, why do they not always cause coming to be continuously rather than sometimes doing so and sometimes not, since there are always both Forms and things that participate in them? Further, in some cases we see something else being the cause; for it is the doctor who produces health in things and the scientific knower who produces scientific knowledge, despite there being health-itself, scientific knowledge-itself, and the things that participate in them. And it is the same way in the case of other things accomplished in accord with a capacity.

On the other hand, if someone were to say that it was the matter that caused coming to be due to its movement, he would speak in a way more appropriate to natural science than those who speak in the way just mentioned; for what alters and changes [something's] shape is more a cause of coming to be, and in all cases we are accustomed to say that the producer, both in the case of what is by nature and what is from craft, is whatever it is that is capable of causing movement. Nonetheless, these people too do not speak correctly; for it is characteristic of matter to be affected and to be moved, while causing movement and producing are characteristic of another capacity. This is clear both in the case of things that come to be by craft and of those that come to be by nature; for the water itself does not produce an animal from itself, nor does the wood produce a bed, but rather craft does. So these people too, because

50. E.g., 100d, 101c.
51. Reference unclear.

of this, speak incorrectly, and because they omit the more controlling cause; for they take away the essence and the shape [or form].

Further, the capacities they assign to the bodies, due to which they cause coming to be, are too instrumental, since they do away with the cause that is in accord with the form. For since, as they say, it is natural for the hot to disaggregate and for the cold to cause coming together, and for each of the others, either to affect or be affected, they say that from these, and because of these, all the others come to be and pass away. It is evident, however, that even fire itself is moved and affected. Further, what they do is much the same as if someone were to assign a saw and each of the instruments as the cause of things' coming to be; for it is necessary for the wood to be divided when someone saws it, and to be smoothed when someone planes it, and similarly in the other cases. So however much fire affects and moves something, in what way it moves it these thinkers do not go on to consider, [nor] that [it is] worse than the instruments. **336^{a}1**

We have spoken[52] in universal terms about the causes previously, and have now made determinations about matter and shape [or form].

2.10
Efficient Cause of Coming to Be and Passing Away: The Sun's Movements

Further, since it has been proved[53] that spatial movement is eternal, it is necessary, these things being so, for coming to be to occur continuously as well; for the spatial movement will produce coming to be perpetually through bringing to and bringing away what is capable of causing coming to be. At the same time, it is clear that what was said previously[54] was correct, namely, saying that spatial movement, and not coming to be, was the primary [sort of] movement; for it is much more reasonable for what is to be the cause of the coming to be for what is not than for what is not to be the cause of being for what is. But what is spatially moving is, while what is coming to be is not. That is why indeed spatial movement is prior to coming to be.

But since we have posited and proved that things are subject to continuous coming to be and passing away, and since we say that spatial movement is the cause of coming to be, it is evident that if the spatial movement is one, it will not be possible for both processes to occur, because they are contraries (for what is the same, and remains in the same state, by its nature always produces the same thing, so that either coming to be will always occur or passing away will), so the spatial movements must

52. *Ph.* 2.3, 7.
53. *Ph.* 8.7–9.
54. *Ph.* 8.7.

be more than one and must be contraries, either because of the direction [of their
30 movement] or because of its irregularity; for contraries have contraries as their causes.

That is why it is not the primary spatial movement that is the cause of coming to be and passing away, but the one in the inclined circle; for in this there is both continuity and being moved with two movements; for it is necessary, if coming to be and passing away are always to be continuous, for there to be, on the one hand, some-
336ᵇ1 thing that is always moved, so that these changes do not fail, and, on the other hand, for there to be two movements, in order that not only one of the two processes will occur. The spatial movement of the whole, then, is the cause of the continuity, while the inclination is the cause of the approach and retreat; for this results in its becoming
5 further away at one time and closer at another, and, since the distance is unequal, the movement will be irregular. So, if it causes coming to be by approaching and being close, this same thing causes passing away by retreating and becoming further away; and if it causes coming to be by repeatedly approaching, it also causes passing away by repeatedly retreating; for contraries have contraries as their causes, and passing away and coming to be in accord with nature occur in equal periods of time.

10 That is why the times—that is, the lives—of each [sort of] thing have a number that determines them; for there is an order of all things, and every time—that is, every life—is measured by a period, except that it is not the same for all, but shorter for some and longer for others; for, for some things, this period, which is their measure,
15 is one year, while for some it is longer, for others shorter. And it is evident that things we perceive are also in agreement with our arguments; for we see that when the sun is approaching there is coming to be, but when it is retreating there is withering, and each of these in equal time; for the time of withering and of coming to be in accord with nature are equal. But it often happens that things pass away in a shorter time because of
20 the co-blending with each other; for because the matter is irregular, and not everywhere the same, it is necessary for the comings to be of things to be irregular too, some faster, some slower, with the result that, because of the comings to be of these things, others come to pass away. But, as we said, coming to be and passing away will always be
25 continuous, and will never fail to occur, due to the cause we have mentioned.[55]

And it is reasonable that this happens; for we say that in all cases nature always desires what is better, and that being is better than not being (in how many ways things are said to *be* has been stated elsewhere), but this cannot belong to all things,
30 because of their being too far removed from the starting-point, although in the remaining way, the god has completed the whole, and made coming to be perpetual; for in this way being would most of all be connected together, because the closest things to being in the fullest sense are perpetual coming to be and coming to be.

The cause of this, as has often been said,[56] is circular spatial movement; for it alone
337ᵃ1 is continuous. That is also why the other things that change into each other in virtue

55. 336ᵃ32–ᵇ3.
56. E.g., 336ᵃ32–ᵇ3.

of their affections and their capacities—for example, the simple bodies—imitate the circular spatial movement; for when from water air comes to be, from air fire, and from fire water again, we say that coming to be has gone around in a circle, because it turns back again. So even the rectilinear spatial movement is continuous by imitating the circular one.

At the same time, something certain people are puzzled about—as to why it is that, when each of the bodies is spatially moving to its own proper space, the bodies have not become separated out in the unlimited time that has elapsed—is clear from these. For the cause of it is their transition into each other; for if each remained in its own place and was not changed by its neighbor, they would already have been separated out. They change, then, because of the spatial movement's being double; and because of changing it is not possible for any of them to remain in any of the places assigned in the order.

That there is coming to be and passing away, then, and due to what cause, and what the capable of coming to be is and the capable of passing away, is evident from what has been said.

But since it is necessary for there to *be* something if there is to be movement (as was said previously elsewhere); and if movement is always to be, for there always to be something; and if continuous, for it to be one, the same, immovable, incapable of coming to be, and unalterable; and if the movements in a circle are several, for there to be several, but for all of them to be somehow under a single starting-point; and because for time to be continuous, it is necessary for the movement to be continuous, if indeed it is impossible for there to be time without movement (therefore time is the number of a certain continuous movement, therefore of the one in a circle—as was determined in our starting accounts); but is the movement continuous because of the continuity of what is moved or because of the continuity of that in which it is moved (I mean, for example, the place or the affection)?—it is clear surely that it is because of what is moved (for how could an affection be continuous except because of the continuity of the thing to which it belongs—but if it is also continuous because of that in which it is moved, this holds only of the place, since it has a certain magnitude); but of it only the movement in a circle is continuous, in such a way that it is always continuous with itself; therefore that is what produces continuous movement, namely, the body spatially moving in a circle, and its movement produces time.

2.11
Necessity in the Sphere of Coming to Be and Passing Away

But since in the case of things that are in continuous movement in virtue of coming to be, or alteration, or change in general, we see that what is successive (that is, *this* coming to be after *that* in such a way as not to leave intervals), it must be investigated whether there is something, or nothing, which of necessity will be, but everything **$337^{b}1$**

admits of not having come to be. For that some do is clear, and the fact that *will be* and *is going to be* are distinct is directly due to this; for of a thing of which it is true to say that it will be, it must at some time be true to say that it is. On the other hand, of that of which it is now true to say that it is going to be, there is nothing to prevent its not having come to be; for someone who is going to take a walk may not take a walk. And, in general, since some beings admit also of not being, it is clear that the same will hold also of things coming to be—that is, their coming to be will not occur of necessity. Are, then, all of them of this sort? Or not so, but rather it is unconditionally necessary for some of them to come to be, and just as in the case of being some are incapable of not being while others are capable, is it that way too with coming to be? For example, is it necessary for solstices to have come to be—that is, is it impossible for them not to admit of not doing so?

If it is necessary for what is earlier to have come to be, if what is later is to do so (for example, if a house, a foundation, and if a foundation, clay), does it also follow, then, that if a foundation has come to be, it is necessary for a house to have come to be? Or is this no longer so, unless it is unconditionally necessary for the latter to have come to be? In this case, if a foundation has come to be, it is also necessary for a house to have come to be; for the relation that the earlier has to the later was [assumed to be] such that if the latter is to be, it is necessary for the former to be earlier. If, therefore, it is necessary for the later one to have come to be, it is also necessary for the earlier one, and if for the earlier one, it is therefore necessary for the later one—not, though, because of the earlier one, but because it was assumed that of necessity it will be. Therefore, in those cases where it is necessary for the later to be, it converts—that is, always, if the earlier has come to be, it is necessary for the later to have come to be.

If, then, it goes on without limit downward,[57] it will not be unconditionally necessary for *this* one of the later ones to have come to be, but hypothetically so; for always it will be necessary for there to be another before it, because of which it is necessary for it to have come to be. So if there is no starting-point of what is unlimited, there will be no first thing because of which it will be necessary for it to have come to be. But then even in the case of the ones that have a limit it will not be true to say that it is unconditionally necessary for it to have come to be (for example, a house when a foundation has come to be; for when a foundation has come to be, it is not always necessary for the house to have come to be), the result will be that something always is, although it admits of not always being. But if something's coming to be is of necessity, it must always be by coming to be; for "necessary" and "always" go together (for what it is necessary for there to be cannot not be), so that if it is of necessity, it is eternal, and if it is eternal, it is of necessity. And if coming to be is therefore of necessity, the coming to be of this is eternal, and if eternal, of necessity.

If, therefore, the coming to be of something is of unconditional necessity, it is necessary for it to close the circle and turn back again. For it is necessary for coming

57. I.e., toward the future.

to be to have a limit or not, and if not, for it to be rectilinear or in a circle. But of these, if indeed it is to be eternal, it cannot be rectilinear, because of there being no starting-point of any sort, whether taken going downward (going toward the future) or upward (going toward the past). But it is necessary for coming to be to have a starting-point, and—not being limited—to be eternal. That is why it is necessary for it to be in a circle.

It is necessary, therefore, for it to convert—that is, if of necessity *this*, therefore also the earlier; moreover, if the earlier, it is also necessary for the later to have come to be. And this goes on always continuously; for it makes no difference whether we say it is because of two things or of more. It is in movement and coming to be in a circle, therefore, that there is unconditional necessity. And if it is in a circle, it is necessary for each thing to come to be and to have come to be, and if this is necessary, the coming to be of these things is in a circle.

This is certainly reasonable, since it was also evident on other grounds[58] that movement in a circle—that is, that of the heaven—is eternal, because those things of necessity come to be and will be that are movements belonging to it and movements due to it; for if what is moved in a circle moves something always, it is necessary for **$338^{b}1$** the movements of these things to be in a circle as well—for example, since the highest spatial movement is produced in a circle, the sun moves in this circular way, and since it moves in this way, the seasons come to be in a circle because of it and turn back again, and since these come to be in this way, so in turn do the things due to them.

Why, then, is it that some things manifestly come to be in this way (for example, rain and air come to be in a circle, and if there is to be cloud, it must rain, and if rain, there must also be cloud), while human beings and animals do not turn back on themselves, so that the same one comes to be again? For it is not necessary, if your father has come to be, that you have come to be; but if you did, he did. And it seems that this coming to be is rectilinear. The starting-point of the investigation, for its part, is to ask again whether all [such processes] turn back on themselves or not, but rather some do so in number, others only in form. It is evident, then, that the things whose substance (the thing moved) is incapable of passing away will be the same in number (for the movement follows along with the thing moved), while those whose substance is not so, but rather is capable of passing away, necessarily turn back again in form, but not in number. That is why the water that comes from air and the air that comes from water are the same in form, not in number. But if these too are the same in number, still it is not by being things whose substance comes to be—that is, being [substance] of the sort that admits of not being.

METEOROLOGY*

BOOK 1

1.1
Scope of the Inquiry

The primary causes of nature, all natural movement, the stars arranged in the upper spatial movement, and the elements of bodies, how many they are and of what sorts, the change into each other, and coming to be and passing away in general, have been spoken about previously. It remains, then, to get a theoretical grasp on a part of this methodical inquiry, which all our predecessors have called "meteorology." It is concerned with whatever things happen in accord with nature, but a nature more disorderly, certainly, than the primary element of the bodies, and which occur in the place nearest to the spatial movement of the stars—for example, the Milky Way, comets, and moving and burning phenomena. It is also concerned with whatever affections may be regarded as common to air and water, and further the parts and forms of earth and the affections of the parts, on the basis of which we may get a theoretical grasp on the causes of winds, earthquakes, and whatever occurs in accord with their movements. Some of these we puzzle over, while others in a certain way we grasp. Further, it is **339ª1** concerned with the fall of lightning bolts, tornadoes and fire-tornadoes, and whatever other recurrent affections of these same bodies as are due to solidification.

After we have discussed these things, let us then get a theoretical grasp on whether we can give some account, in the way we have laid down, of animals and plants, both universally and separately. For when we have stated it, all of what we deliberately chose for ourselves at the start would pretty much have reached its end.

Having made a start in this way, let us speak about the following things first.

1.2
Introduction to the Material and Efficient Causes

We previously determined that there is one starting-point of bodies, from which the nature of the bodies in circular spatial movement is composed, but four other bodies

* Books 1.1–3 and 4 translated by C. D. C. Reeve. Books 1.4–14, and 2–3 translated by Malcolm Wilson. Text: F. Fobes, *Aristotelis Meteorologicorum Libri Quattuor* (Cambridge, MA, 1919).

that are due to four starting-points, the movement of which, we say, is twofold, either away from or toward the center.[1] These four are fire and air, water and earth, and fire is what always rises to the top of them, while earth is what sinks down, while the other two stand to each other in a proportional relation (for air is nearest of all to fire, water to earth).[2] Since the whole cosmos around the earth, then, is composed of these bodies, the coincidental affections belonging to which, we say, must be grasped. It is of necessity continuous with the upper spatial movements, so that all its capacity [for movement] is governed from there. (For where the starting-point of all movement is from, that must be considered the primary cause. In addition to this, it is eternal and it has no end as regards the place of its movement, but is always at its end, while these other bodies all have limited places that are separate from each other.) So, as it concerns what takes place in the cosmos, fire, earth, and what is of the same kind as these must be regarded as the kinds of in-matter cause of the things that come to be (for the underlying affected subject is what we refer to in this way), while in the sense of the cause from which, that is, the starting-point of movement, one must assign causality to the capacity of the things that are always moving.

1.3
An Inquiry into the More Appropriate Causes

Let us take up again our initial posits and the distinctions stated previously and then discuss the appearance of the Milky Way and comets, and whatever other things are of the same kind as these.

We say, then, that fire, air, water, and earth come to be from each other, and that each is potentially present in the other, just as in the case of other things in which one and the same something underlies, into which they are at last resolved.[3]

339b1 First, someone might raise a puzzle about the so-called air, as to what we must take its nature to be in the cosmos encompassing the earth, and what its position in the order is in relation to the other so-called elements of bodies. (For how great the mass of the earth is in relation to the encompassing magnitudes is certainly not unclear. For astronomical observations have already shown to us that the earth is far smaller even than some of the stars; while we never see the nature of water collectively and marked off by boundaries, nor does it admit of being separated from the body settled around the earth—for example, the evident cases of the sea and rivers, and any that there may be below [the earth] and unclear to us.) But intermediate between the earth and the outermost stars must we consider there to be a body of a single nature or several? And if several, how many, and as far as where do their places extend?

1. *Cael.* 1.2–4.
2. *GC* 330b30–331a3.
3. *GC* 331a7–8, 334b2–30, *Cael.* 3.6.

We have spoken previously about the primary element, of what sort it is in virtue of its capacity, and why all of the cosmos around the upper spatial movements is filled with that body.[4] And we do not happen to be the only ones to hold this belief. For it appears to be an ancient supposition and one held previously by human beings, since so-called *aithêr* [ether] was given this name in antiquity. Anaxagoras seems to me to think that it signifies the same thing as "fire."[5] For he thought that the upper regions are full of fire, and that the ancients[6] called the capacity there *aithêr*. And on this latter point he believed correctly. For people seem to have supposed that the body that is always running (*aei theon*) is at the same time in a way divine (*theion*) in nature, and decided to name something of this sort *aithêr*, as not being the same as any of the things around us.

For we say that the same beliefs come about in cycles among human beings, not once or twice or a few times, but an unlimited number of times.

On the other hand, those who say that not only the bodies in spatial movement but also what encompasses them are pure fire, and that what is intermediate between the earth and the stars is air, would perhaps have ceased to hold this childish belief if they had got a theoretical grasp on what mathematics has now adequately shown. For it is too simple to consider each of the spatially moving things to be small in magnitude, because it appears so to us when we look at it from here. We have also spoken about these matters previously in our speculations about the upper place.[7] But let us state the same account again now.

If the intervals were full of fire and the bodies were composed of fire, each of the other elements would long ago have vanished. But then neither are they full of air alone. For then air would far exceed the equality of its common proportion in relation to the co-ordinate bodies, even if two elements filled the place intermediate between earth and heaven. For the mass of the earth, in which the whole quantity of water is also comprised, is (one might almost say) nothing in comparison to the encompassing magnitude. However, we see the excess between their masses not to be of such a magnitude when air becomes disaggregated from water or fire from air. But it is necessary for the same ratio (*logos*) to hold between however small a quantity of water and the air coming to be from it as holds between the totality of air and the totality of water. And it makes no difference if someone will deny that these come to be from each other, yet allows that they are equal in capacity.[8] For on this way of proceeding it is necessary for the equality in capacity to belong to their quantities, just as it would have belonged if these came to be from each other. It is evident, then, that neither fire nor air alone fills the intermediate place.

8. E.g., Empedocles B17.27 DK.

It remains, after having gone through the puzzles, to say in what way the two—I mean air and fire—are ordered in relation to the position of the primary body, and due to what cause the heat from the stars above reaches the places around the earth. Let us speak about air first, then, as we proposed, and in turn speak in this way also about these [other things].[9]

If water comes to be from air and air from water, why are no clouds composed in the upper place? For it would be more fitting for them to be composed the farther the place is from the earth and the colder it is, due to its not being that close to the heat of the stars nor to the rays reflected from the earth, which prevent clouds from being composed near the earth, by disaggregating their composition because of the heat. For cloud gatherings occur where the rays already abate because of their dispersal into the vastness.

Either, then, water does not naturally come to be from all air, or, if it comes from all of it alike, the air surrounding the earth is not air alone but rather a sort of vapor, which is why it gets composed into water again. But then if however much air there is, is all vapor, the nature of air and the nature of water would seem to be too excessive [in quantity], if indeed the intervals between the things above must be filled with some body, and if this cannot be fire because all the others would have been dried up if it were. And it remains for it to be air and all the water surrounding the earth, since vapor is disaggregated water.

About these things then let the puzzles be gone through in this way. For our part, let us speak at once with a view to the determinations that have already been stated and with a view to the ones we are now to state. For we say that what is upper and as far as the moon is a body distinct from fire or air, but varying in itself in purity and freedom from admixture, and admitting of differences, especially insofar as it stops before the air and the cosmos surrounding the earth. The circular spatial movement of the primary element and the bodies set in it disaggregate and ignite by their movement the part of the lower cosmos and body that is each time nearest to it, and so produce heat. And we must also understand it in this way even if we start as follows. For the body below the upper circular movement is like a sort of matter, and is potentially hot, cold, dry, wet, and whatever other affections follow along with these. But it becomes these and [actually] is them due to movement and immobility, the cause and starting-point of which we spoke previously.[10] At the center and around the center what is heaviest and coldest is set apart, namely, earth and water. Around these, and continuous with them, are air and what due to custom we call "fire," but it is not fire. For fire is excess of hotness and a sort of boiling. But we must understand that, of what we call "air," the part surrounding the earth is, as it were, wet and hot because it is vaporous and contains exhalations from the earth, while the part above this is already

9. 339b3.
10. *GC* 336b27–34.

hot and dry. For vapor's nature is wet and cold,[11] that of exhalation hot and dry. And vapor is potentially like water, exhalation potentially like fire. We must suppose, then, that the cause of clouds not being composed in the upper place is that air alone is not present in it but rather a sort of fire. But there is nothing to prevent its being also due to the circular spatial movement that clouds are prevented from being composed in the upper place. For the totality of air encircling the earth is necessarily flowing, except that part of it caught within the circumference that evens it out, so that the earth is entirely spherical. (For it is evident as things stand that the winds occur in marshy places of the earth, and do not seem to blow above the highest peaks.) This air flows in a circle because it is drawn along by the circular spatial movement of the whole. For the fire is continuous with the upper element and the air is continuous with the fire. So it is their movement too that prevents them from being composed into water. Instead, always, whatever part becomes heavy, the heat in it is squeezed out into the upper place and it travels downward, but other particles in turn travel upward together with the fiery exhalation, and in this way it is continually the case that while one layer is always full of air and the other of fire, each of them is always in constant flux.

About why clouds do not occur, why the air [there] is not aggregated into water, how one must conceive of the place intermediate between the stars and the earth, and what sort of body it is filled with, let this much be said.

As for the generation of heat that is provided by the sun, it is more fitting to speak about it intrinsically and exactly in the studies concerning perception[12] (for heat is a sort of affection of perception), but due to what sort of cause it comes to be, though the nature of the things there [where the sun is] is not of this sort, must be stated now.

We see, then, that movement is capable of disaggregating and igniting air, so that even things in spatial movement often manifestly melt. The sun's spatial movement alone, then, is sufficient by itself to make it happen that warmth and heat are produced. For to do so it must be fast and not too far away. The spatial movement of the [fixed] stars, though fast, is far off, while that of the moon, though close by, is slow. But that of the sun has enough of both characteristics. That more heat should be generated when the sun itself is there is reasonable, if we take the similarity from what comes about where we are. For here too it is the air that is closest to what is spatially moving by force that becomes most hot. And this happens quite reasonably. For the movement of a solid object disaggregates the air most. This, then, is one cause due to which heat reaches this place here. Another is that the fire encompassing the air is often dispersed by the [sun's] movement and by force carried downward.

An adequate sign that the upper place is not hot or fiery is also provided by the course of the [shooting] stars. For they do not come about there but below. And yet

11. Reading ψυχρόν.

12. No discussion of the felt heat of the sun, as such, is found in *DA* or *Sens.*, but there is an account of how we perceive hot and cold, and the heat of the sun is presumably a special case of this.

the more and the faster things move, the faster they ignite. In addition to this, the sun, which is the very thing that seems to be the most hot of all, is manifestly white but not fiery.

1.4
Fiery Celestial Phenomena

341ᵇ1 Now that we have laid down these distinctions, let us discuss the cause due to which the burning flames appear in the heaven, as well as shooting stars, and the "torches" and "goats" as they are called by some.[13] For all of these things are the same and exist due to the same cause, though they differ by the more and less.

The starting-point of these things and many others is the following: when the earth is heated by the sun, there necessarily occurs not one simple exhalation, as some[14] think, but two; the one more vaporous, the other more like wind; the first, a vapor from the liquid in and on the earth; the latter, smoky, since the earth itself is dry. And of these two, the wind-like one rises to the top because of its heat, and the wetter one sinks because of its weight. Because of this, the surrounding space is ordered in this way: first under the circular movement is the hot and dry, which we call "fire" (for what is common to all the smoky disaggregation has no name, but because it is the nature of this sort of thing to be ignited more than all other bodies, it is necessary to apply the names in this way); and under this nature, is the air. So, we must think of what we just now called "fire" as a fuel, which is extended throughout the remotest part of the sphere surrounding the earth, so that if it encounters a slight movement, it often ignites like smoke does. For flame is the boiling of a dry wind. So, wherever this composition is just right, it ignites, whenever it is moved in some way by the periphery.

There are differences, though, in accord with the position or amount of the fuel. If the fuel has breadth and length, a flame is often seen burning as in a field of burning stubble; but if it [burns] in length alone, they are the so-called torches and goats and [shooting] stars. And if the fuel is greater along the length than the breadth, whenever it emits sparks, as it were, as it burns (and this occurs because of side-ignitions which, albeit little, are at the starting-point) it is called a "goat," but whenever it occurs without this affection, it is called a "torch." And if the lengths of the exhalation are scattered in little bits and in many places and equally in breadth and depth, there come to be stars that seem to dart.

Sometimes the exhalation gives rise to them, when it is ignited by the movement; but sometimes the hot material is squeezed out and expelled by air when it gets **342ª1** composed due to the cold; that is why their spatial movement seems to be more like

13. Identity unknown.
14. E.g., perhaps Anaximenes B2, Xenophanes B30 DK.

an ejection and not an ignition. For one might be puzzled as to whether it is like the exhalation placed under lamps, which ignites the lower lamp from the flame above (for the speed of this effect too is wondrous, and similar to an ejection, and not like a fire that is in a constant process of change) or whether the shooting stars are ejections of the same sort of body. Indeed, they seem to come about due to both things: they occur just as they do from the lamp, and some are ejected due to being squeezed out like pips from between the fingers, so that they are seen to fall to the earth and to the sea, at night and during the day and when it is clear. They are ejected downward, because the condensation pushes them out and inclines them downward. Because of this too, lightning bolts are thrown downward.[15] For the coming to be of all these things is not ignition, but expulsion by squeezing out, since by nature, at any rate, all hot things have a tendency to travel upward.

The group of things that get composed more in the uppermost place occur when the exhalation is ignited; but the things further down do so when the exhalation is expelled, because the wetter exhalation comes together and is cooled. For this exhalation, as it comes together and condenses, inclines downward, pushes out the heat and ejects it downward. And it travels up or down or to the side due to the position of the exhalation, and however its breadth and depth happen to be oriented. Most often, it moves to the side, because there are two spatial movements involved, the one by force downward and the other by nature upward; for all such things move spatially along the diagonal. Because of this, the spatial movement of the shooting stars is most often aslant.

So, the cause, as matter, of all these things is the exhalation, but, as mover, it is sometimes the upper spatial movement, sometimes the solidification of the air as it aggregates. And all these things happen below the moon. A sign of this is that their apparent speed is similar to things we throw, which, because they are near to us, seem much to surpass in speed the stars and the sun and the moon.

1.5
The Aurora

On a clear night there sometimes appear many phenomena being composed in the heaven, such as chasms and trenches and bloody colors. The cause in these cases is the same: since the upper air is manifestly being composed in such a way as to catch fire, and the ignition occurs in such a way that sometimes a flame seems to burn, and **342b1** sometimes torches, as it were, and stars seem to travel, there is nothing extraordinary if this same air takes on a variety of colors when it is being composed. For the light that appears less intense when passing through a denser medium and the air that undergoes reflection will produce various colors and especially crimson or purple,

15. Omitting τοῦ πυρὸς . . . φύσιν.

because these especially appear, when fiery-yellow and white are mixed by being placed one in front of the other, just as stars appear crimson through the smoke, if it is very hot as they rise and set. They will also produce them by reflection, whenever the mirror is such as to receive not the form but [just] the color. The cause of these things not remaining for a long time is that their composition is swift.

When the light is breaking out from blue and black, it makes the chasms seem to have a sort of depth. And from such formations, torches too are often ejected, whenever there is more aggregation [of the air]. When it is still coming together, a chasm appears. And in general, the white produces a great variety of colors against the black, as with a flame in smoke. The sun prevents their appearance during the day, but during the night no other colors appear except crimson due to their similarity of color.

So, concerning the shooting stars, what catches fire, and again concerning other such phenomena that make swift appearances, one must suppose these to be the causes.

1.6
Comets (1)

Let us discuss the comets and the so-called Milky Way, by first going through the puzzles that arise from what has been said by others.

Anaxagoras and Democritus claim that comets are a conjunction of planets, when, because of their coming close, they seem to touch one another.

Among the Italians, some of the Pythagoreans, as they are called, say that it is one of the planets and that it makes its appearance at lengthy intervals of time and its rise above the horizon is short, which is precisely what happens with Mercury too. For because of its short rise above the horizon, it misses many appearances, so that it appears after a great interval of time.

Hippocrates of Chios, his student Aeschylus, and their associates make much the same claims as these, except they say that [the comet] does not have a comet in its
343a1 own right, but that, as it wanders, it sometimes acquires one due to its place, because our ray of sight is reflected to the sun from the liquid which is being dragged by the comet. And because the comet lags behind [the sun] most slowly in terms of time, it makes its appearance after a longer interval than the other planets (*astrôn*), since whenever it appears again in the same place, it has lagged behind the whole of its own circle. And it lags behind both toward the north and toward the south. In the place between the tropics it does not draw water to itself, because the water has been burned up by the spatial movement of the sun. And whenever it travels toward the south, it has an abundance of this sort of liquid, but because the section of the circle above the earth is small, and that below is many times the size, the human ray of sight is not able to be reflected and carried to the sun, neither when the sun is near the

tropical place nor when it is at the summer tropics. Because of this, it does not take on a comet in these places; but whenever it happens to lag behind toward the north, it acquires a comet, because the circumference above the horizon is great, while the part of the circle below the horizon is small. For the human ray of sight then reaches the sun with ease.

All these theories make impossible claims, some common, others particular.

First, then, [let us deal with] those who say that the comet is one of the planets; for all the planets lag behind in the circle of the zodiac, while many comets have been seen outside of the circle. Next, more than one have occurred together on many occasions. In addition, if they get their comet because of reflection, as Aeschylus and Hippocrates say, it would be necessary for this planet to appear at some time without a comet as well, since it lags behind in other places too, but it does not everywhere have the comet. But as it is, no other planet has been seen except the five. And these often appear well above the horizon all at the same time. And both when all these planets are visible, and when some are not visible because of being close to the sun, the fact remains that we often see comets occur. But again, it is not even true that a comet occurs only in the region toward the north, at the same time as the sun is around the summer tropics. For the great comet, which came to be at the time of the **343b1** earthquake in Achaia and the onslaught of the wave, rose from the equinoctial sunset; and many have occurred in the north. And in the archonship at Athens of Euclees, son of Molon, a cometic star came to be toward the Bear in the month of Gamelion,[16] when the sun was at the winter tropics. And yet even they claim that reflection to such a distance is something impossible.

The first objection common to these people and to those who say the comet is a conjunction is that even some of the fixed stars acquire a comet. One need not trust the Egyptians alone on this point, and yet they too affirm it: we ourselves have beheld it. For one of the stars in the groin of the Dog had a comet, though it was dim; for if you looked directly at it, its light was dim; but if you looked aside and less intensely, it was brighter. And in addition, all the comets that have been seen among us have vanished in the place above the horizon without setting, fading gradually in such a way that no body of a single or several planets lag behind. For the big star, that we mentioned previously,[17] also appeared during the winter in frosty and clear weather off the west, when Asteios was archon,[18] and on the first day it was not seen, since it had set before the sun did, but on the next day it was seen. For it lagged behind by the smallest possible extent and set straightaway. Its light extended over a third of the heaven like a cord,[19] which is why it was called a "path." It made its way up to the belt of Orion and there it dissolved.

16. January–February 426 BC.
17. 343b1.
18. 373–372 BC.
19. Reading ἅμμα.

And yet Democritus, at any rate, clung to his own opinion. For he says that some heavenly bodies (*asteras*) have been seen upon the dissolution of comets. But this ought not to happen just sometimes and not at other times, but always. And in addition, the Egyptians also claim that conjunctions of the planets with each other and with the fixed stars occur—and we ourselves have seen Jupiter[20] coming together with one of the stars in the Twins at one point and then disappearing—but no comet came to be.

Further, the matter is also evident from argument. Whether the heavenly bodies appear larger or smaller, they nonetheless appear to be intrinsically indivisible. So, just as they would produce no greater magnitude when they touch, if they were indivisible, so also, since they are not, but only appear to be indivisible, when they come into conjunction, they will not appear greater in magnitude. So, it is sufficiently clear through these arguments, at any rate, if not through others, that the stated causes about them happen to be false.

1.7
Comets (2)

Since we think that we have given a sufficiently rational demonstration about things inaccessible to perception, if we lead them back to what is possible, one might suppose from what is now apparent that these things occur pretty much in the following way.

We have laid down that the first part of the cosmos that surrounds the earth and is under the circular spatial movement is dry and hot exhalation. This exhalation, both itself and the greater part of the air that is continuous with and underneath it, is carried around the earth by the circular spatial movement. And when it is carried and moved in this way, it often catches fire, where it happens to be well mixed. That is why we claim that the sporadic shooting stars occur.

Whenever, then, as a result of the movement from above, a fiery starting-point falls into such a condensation, and it is not so great that it burns [the material] quickly and extensively, nor so feeble that it is extinguished quickly, but is larger and more extensive than that, and at the same time there happens to arise from below a well-mixed exhalation, then this star becomes cometic, and in whatever shape the exhalation happens to have been formed. If it is formed similarly in all directions, it is a comet; but if its length is greater, it is called a "bearded star." And just as the spatial movement involved seems to be the movement of a star, so also the immobility seems to be the immobility of a star. For what occurs is much the same as if one were to thrust a torch into a heap and mass of chaff or throw a small starting-point of fire upon it. The shooting stars seems to be like this; for they spread quickly along their

20. Perhaps in December 337 BC.

length because of the good condition of the fuel. So, if this [starting-point] should remain in place where the fuel is densest and does not fade away due to passing through, the end of its course would be the beginning of its spatial movement. A cometic star is just like a star's shooting, but having in itself the end and the starting-point.[21]

Whenever the starting-point of the composition is in the lower place itself, it appears as a comet by itself. But whenever it is under a heavenly body, either a fixed star or a planet, and the exhalation gets composed because of the movement [of the star], then one of these may become a comet. For the comet does not form on the stars themselves, but it forms like the haloes that appear around the sun and the moon to accompany them, even though they are changing place, whenever the air takes on the right density for this affection to occur under the path of the sun; it is in this way that a comet is like a halo for the stars, except that a halo comes to have its color by reflection, while in this case their color is the one that appears upon them.

Whenever such an aggregation occurs in association with a star, the comet must be seen to move with the same spatial movement the heavenly body has. But whenever it is composed by itself, it is seen to lag behind. For such is the spatial movement of the cosmos surrounding the earth. For the fact that a comet often arises just by itself, and indeed does so more often than around certain determinate stars, makes patently clear that the comet is not a sort of reflection, as if it were a halo associated in pure fuel with the star itself rather than, as the Hippocratics say, associated with the sun. The cause of the halo we shall discuss later.[22]

When comets are numerous, they are a sign of wind and drought, and we must suppose that this is a proof that their composition is fiery. For it is clear that comets occur because this sort of emanation is great. The result is that the air must be drier, and the liquid which is being vaporized must be disaggregated and dissolved by the mass of the hot exhalation, so that it cannot be composed easily into water. We shall speak more plainly about this affection too, when it is time to talk about winds.[23]

Whenever comets appear dense and numerous, as we said,[24] the years are conspicuously dry and windy; but when the comets are less frequent and dimmer in terms of magnitude, this sort of thing does not occur in the same way; but all the same, there is for the most part some wind that exceeds in terms of time or magnitude, since when the stone fell in Aegospotami from the air,[25] it was raised up by the wind and fell in broad daylight. At that time a cometic star happened to arise from the west. And around the time of the great cometic star the winter was dry and with winds out of the north, and the tsunami arose from an opposition of winds. For in the gulf a north wind held sway, but outside it the south blew strongly. Again, in the

21. I.e., it burns in a single place and does not shoot.
22. 3.2–3.
23. 2.4–6.
24. 344b20.
25. The famous meteorite of 467 BC.

345a1 archonship of Nicomachus,[26] a comet occurred for a few days around the equinoctial circle, not rising from the west, and under these conditions the wind around Corinth happened to arise.

As for the fact that comets are not numerous or frequent, and more outside the tropics than inside, the cause is the movement of the sun and the heavenly bodies, which not only expels the hot [material], but also disaggregates the composition [of the dry exhalation]. But the most important cause is that most [of the exhalation] gathers into the space of the Milky Way.

1.8
The Milky Way

Let us discuss at this point how and through what cause the Milky Way comes about and what it is. But first let us go through the things said by others about it. Some of the so-called Pythagoreans claim that it is a path—some claiming that it is the path of one of the fallen stars according to the storied destruction of Phaethon; others claim that the sun once traveled on this circle and that as a result this place was thoroughly burnt, as it were, or suffered some other such affection as a result of its[27] spatial movement.

But it is strange not to realize that if this were in fact the cause, the circle of the zodiac would also have to be so affected—indeed, more so than the circle of the Milky Way, since all the planets travel along it and not just the sun alone. And the whole circle of the zodiac is apparent to us; for its semicircle is always apparent during the night. But it has obviously suffered no such effect, except where some part of it touches the circle of the Milky Way.

The associates of Anaxagoras and Democritus[28] say that the Milky Way is the light of certain stars; for the sun, when it travels below the earth, does not see some of the stars. The light of those stars that are visible from the sun does not appear (for it is blocked by the rays of the sun). But, they claim, the Milky Way is the light proper to the stars, which the earth blocks off from being visible from the sun. But this too is clearly impossible; for the Milky Way is always the same and is associated with the same stars (for it is clearly a greatest circle), but the stars that are not visible from the sun are constantly changing, because it does not stay in the same place. So, the Milky Way would necessarily change place, as the sun changes place. But as things stand, it is evident that this does not occur.

345b1 In addition, if, as is now proved in astronomical speculations, the size of the sun is greater than the size of the earth, and the distance from the stars to the earth is many times greater than the distance of the sun [to the earth] (just as the distance of the

26. 341–340 BC.
27. Reading αὐτοῦ.
28. Anaxagoras A1, Democritus A91 DK.

sun to the earth is greater than that of the moon [to the earth]), the cone from the sun would cause its rays to converge not far from the earth, nor would the shadow of the earth, what we call "night," be near to the stars. Rather, the stars are necessarily all visible to the sun, and the earth cannot block off any of them.

Further, there is a third supposition about it. For some say that the Milky Way is a reflection of our ray of sight to the sun, just as with a cometic star.

But this too is impossible. For if the observer, the mirror, and what is seen in its entirety are at rest, the same part of the reflection would appear at the same point of the mirror. But if the mirror and what is seen move in the same interval [of space] relative to the observer, who is at rest, but neither with equal speed nor with the same constant distance relative to each other, it is impossible for the same reflection to be in the same part of the mirror. But the stars that travel in the circle of the Milky Way, as well as the sun, toward which the reflection occurs, move, while we stay at rest; and while they keep a similar and equal distance in relation to us, they do not maintain an equal distance in relation to each other. For sometimes the Dolphin rises in the middle of the night, but sometimes at dawn, but the parts of the Milky Way remain the same at each time. And yet this should not be the case, if the Milky Way were a reflection, and not some [real] affection in the very places [it appears].

Further, at night the Milky Way appears when we look at it in water and similar mirrors, but how can the ray of sight be reflected to the sun?

From this it is clear that it is neither the path of any of the planets, nor is it the light of the stars that are not visible [to the sun], nor is it a reflection. These are pretty much the only theories that have been handed down by others up to the present time.

But let us speak by making reference to the starting-point that has been laid down by us. For we said previously[29] that the remotest part of what we call "air" has the capacity of fire, so that when the air is disaggregated by the [upper] movement, there is separated off a sort of composition, and this we claim to be the cometic stars. So, we must suppose that what is happening here came to be in the case of the cometic stars, when this sort of segregation came to be not alone by itself, but due to one of **346^{a}1** the heavenly bodies, either the fixed or the wandering ones. For these appear under these circumstances as comets, because they follow [the stars'] spatial movement, whenever the air happens to be mixed appropriately, just as the sort of aggregation, from which we claim the halo appears by reflection, [follows] the sun. We must suppose that what happens with one of the stars occurs with the whole of the heaven and the entire upper spatial movement. For it is reasonable that, if the movement of a single star produces some such effect, the movement of all the stars should do so too, and fan {the air and disaggregate it because of the magnitude of the circle.}[30] {It is necessary that among the same greatest circles the spatial movement that is especially going to produce this. . . . For this is necessary, in order to produce a movement that

29. 340^{b}29.

30. Omitted in the better mss.

is great because of its magnitude and to make the ignition greater.}[31] And in addition, they do so in the place where there happen to be the densest, most numerous, and largest stars.

The circle of the zodiac dissolves this sort of composition because of the spatial movement of the sun and the planets. This is why, indeed, most of the comets occur outside of the tropics. Further, a comet does not appear either around the sun or around the moon; for they disaggregate [them] too quickly for a composition of this sort to form. But the circle in which the Milky Way appears when we look at it happens to be the largest and to lie in such a position that it extends far beyond the tropics.

In addition, the place is full of the biggest and brightest stars, indeed full of what we call the "sporadics" (and this is clear to see with our eyes); and so because of this, all this aggregation is continually and constantly gathered together. And this is a sign of the fact: on the circle [of the Milky Way] itself the light is greater in the semicircle which has the doubling. For in this half the stars are more numerous and denser than in the other half, indicating that the light came to be due to no other cause than the spatial movement of the stars. For if it came to be in the circle in which the greatest number of the stars lay and in the part of that very circle in which it appears to be denser in both the magnitude and the quantity of stars, it is reasonable to assume that this is the most proper cause of the affection.

The circle and the stars in it may be seen from the diagram. As for the so-called sporadics, it will not be possible to arrange them in this way on the sphere because none of them has an evident permanent position, but they are clear when you look at the heaven. For in this one alone of the circles the areas in between are full of such stars, but in the others they are manifestly intermittent. So, if we accept that the cause of the appearance of comets has been stated in a reasonable way, we must assume that it is the same with the Milky Way too. For the affection that, in this case, the comet manifests concerning one star happens to be the same concerning a certain sort of circle; and the Milky Way, to speak in the manner of a definition, is the comet of the biggest circle and is due to segregation. That is why, just as we said previously, comets are not numerous, nor do they occur often, because this sort of composition has been and is continually being separated off in each cycle into this place.

We have discussed the things that occur in the cosmos that surrounds the earth and is continuous with the [heavenly] spatial movements, and concerning the shooting stars and the burning flames and again, the comets and the so-called Milky Way. For these are pretty much the affections that make their appearance in this place.

31. Olympiodorus provides this text, which is absent in the mss.

1.9
The Effects of the Wet Exhalation: Precipitation

Let us discuss the place that has the second position after this but the first one around the earth. This is the common place of water and air and of the coincidental affections that attend upon the coming to be [of water] in the upper area. One must suppose that the starting-points and causes of all these things are similar.

The controlling and first starting-point as mover is the circle, in which the spatial movement of the sun manifestly disaggregates and aggregates by getting close or further away and is the cause of coming to be and passing away. While the earth remains at rest, the liquid surrounding it is vaporized and carried up by the rays [of the sun] and the other heat from above. And when the heat, which raises it up, departs, some of it is scattered to the upper place, while the rest of it is extinguished, because it has been elevated too high into the air above the earth. The vapor then cools and is composed again, both because of the departure of heat and because of the place, and water comes to be from air. And after its coming to be, it travels back to the earth. The exhalation from water is vapor, while the one from air to water is cloud. Mist is a residue of a cloud from its aggregation into water. That is why it is a sign of good weather rather than of rain; for the mist is, as it were, a sterile cloud.

And this circle occurs in imitation of the circle of the sun. For as the sun's circle changes direction on the slant, the water cycle goes up and down. We must suppose that it is like a river flowing in a circle up and down, common to air and water; for when the sun is close, the river of vapor flows upward, and when it recedes, the river of water flows downward. And this is naturally disposed to occur continually according to some order. So, if indeed our predecessors[32] were speaking of the Ocean [river] allegorically, perhaps they meant that this is the river that is flowing in a circle around the earth.

And since the liquid is always being raised up because of the capacity of the hot and brought back down to the earth because of the cooling, their names are appropriately applied to their affections and some of their differences. For whenever they move in little portions, they are called "droplets," but whenever they move in greater portions, "rain."

1.10
Dew and Frost

[The liquid] that vaporizes on a daily basis but is not elevated high [in the air], because the fire that draws it up is small in comparison to the water that it raises, falls back down when it is cooled at night, and is called "dew" and "frost." It is called

32. Homer *Iliad* 18.607–608, 21.195–197, *Odyssey* 11.13, 21.

"frost" when the vapor solidifies before it aggregates back into water (and this occurs during the winter and more so in wintry places); and it is called "dew" when the vapor aggregates into water, and the warmth is not so great that the liquid that is raised gets dried out, nor is the cold so great that the vapor itself is solidified, either because the place or the season is warmer. Dew occurs more in good weather and in more clement places, while frost, as has been said, in the opposite conditions. For it is clear that vapor is hotter than water (for it still contains the fire that carries it up), so that greater coldness is required to solidify it. And both occur during clear and windless weather. For [the vapor] will not be raised up, unless there is clear weather; nor could it get composed, if the wind is blowing.

And here is a sign that these occur because the vapor does not rise high: frost does not occur in the mountains. And one of the causes is that [the vapor] is raised up from low-lying and watery places, so that the heat that is lifting it, like a burden too great for itself, is unable to raise it to a place of great height, but drops it back from close by. Another cause is that the flowing air, which dissolves this sort of composition, flows especially in the heights.

Dew occurs everywhere in south winds, but not in north winds, except in Pontus. There the opposite situation holds: dew occurs in the north winds, but not in south winds. The cause is similar to what occurs during good weather, and not during wintry weather. For the south wind produces good weather, while the north wind produces wintry weather. For the north wind is cold, so that as a result of the wintry weather it extinguishes the heat of the exhalation. But in Pontus the south wind does not produce good weather in such a way that vapor occurs, while the north wind undergoes reciprocal replacement because of the cold, and gathers up the heat so that much more vapor is generated. And often it is possible to see this occur in the other places too. For wells produce more vapor in north winds than in south ones. But north winds extinguish it before any quantity is composed, while in south winds the exhalation is allowed to gather. The water itself does not solidify, just as in the place around clouds.

1.11
Correspondences between Rain/Snow and Dew/Frost

For from that place three bodies are frequently composed by cooling: rain, snow, and hail. Among these, two are analogs and occur due to the same causes as the lower ones, differing by the more and less, and by the larger and smaller quantity. For snow and frost are the same, and so are rain and dew, but the first members of the pairs are of large quantity and the second members of small quantity. For the rain occurs when a large quantity of vapor cools, and the cause of this is that both the place and the time, in which and from which [the vapor] is collected, are large. But dew is of a small quantity; for the composition of it occurs daily and the place [from which the

liquid is gathered] is small, as the rapidity of its coming to be and the smallness of its quantity make clear. Likewise, also with frost and snow: for when the cloud solidifies, it is snow, and when vapor solidifies, it is frost. That is why they are the sign of a cold season or region; for when there is still a lot of internal heat, it could not be solidified, unless the cold were in control. For in the cloud there is a lot of heat still present left over from the fire that vaporized the liquid from the earth.

Hail occurs in that [upper] place, but the [analog] is missing in what vaporizes close to the earth. For just as we said, as snow is [up] there, so frost is here; and as rain is [up] there, so dew is here. But as hail is there, here there is no similar corresponding thing. And the cause will be clear when we have spoken about hail.

1.12
Hail

As regards the circumstances of its coming to be, it is necessary to grasp at the same time both those that do not lead to errors and those that seem to be paradoxical.

Hail is ice, and water solidifies in the winter. But hail occurs especially during the spring and fall, and secondarily during the late summer too, but during the winter rarely and whenever there is less cold. And, in general, hail occurs in more clement **348ᵃ1** places, while snow in colder ones.

It is also strange that water should solidify in the upper place. For [vapor] cannot solidify before it becomes water, nor can water remain aloft for any period of time. Nor again does rain rest upon the air, like the droplets do that are carried up because of their small size and spend time in the air—just like earth and gold, too, often float upon water due to the smallness of their parts—and then many small parts come together, and large droplets fall. This cannot occur in the case of hail; for solidified objects do not grow together like wet things do. So, it is clear that a lot of water remained high; for otherwise so great a quantity could not have solidified.

Some people[33] think that the cause of this affection and coming to be is this: when the cloud is pushed up into the upper place, which is rather cold because the reflections from the rays of the sun from the earth peter out there, when the water arrives there, it solidifies. That is why[, they think,] hail occurs more during the summer and in warm regions, because the heat pushes the clouds up from the earth to a greater extent. But it happens that hail occurs least of all in extremely high places. And yet it should, just as we also see snow coming to be especially in high places. And again, often clouds are seen traveling with a great deal of noise so close to the earth itself that they frighten those who hear and see them, since they suppose that something of larger scale is on its way. And sometimes, even when such clouds are seen without the noise, a great hail occurs, unbelievable in its magnitude and not round in shape,

33. E.g., Anaxagoras. See 348ᵇ12.

because the solidification has occurred close to the earth and therefore their spatial movement was brief, and not as those people claim it is.

Surely, big hail must occur by that which is most a cause of solidification; for hail is ice, and this is clear to anyone. And the hailstones that are not round in shape are big. This is a sign that they have solidified close to the earth. For those that have moved from afar become broken off all around, because they have moved a long distance, and become round in shape and smaller in size.

It is clear that the solidification occurs not by being pushed up into the cold upper place. But, since we see that reciprocal replacement occurs between hot and cold (for this reason the things under the earth are cold in warm seasons and warm in cold seasons), we must think that this occurs in the upper place too, so that in the warmer seasons the cold undergoes reciprocal replacement inside because of the heat around it, and sometimes quickly produces water from the cloud. That is also why the droplets become much bigger on warm days than in the winter, and the rain is more violent. For it is said to be more violent when it is more concentrated, and it is more concentrated because of the speed of the condensation. (This is the very opposite to what Anaxagoras claims; for he says that this affection happens [to the cloud] when it goes up into cold air, but we say that it happens when it descends into the hot, and most of all, when it makes the greatest descent.)

But when the cold inside undergoes even further reciprocal replacement by the hot outside, it produces water, solidifies, and becomes hail. And this happens when the solidification is faster than the spatial movement of the rain downward. For if it spatially moves in a certain given time, while the coldness, being intense, brings about the solidification in a shorter time, nothing prevents the solidification from happening while still aloft, if the solidification occurs in a shorter time than the downward spatial movement. And the nearer and the more concentrated the solidification is, the more violent is the rain, and the bigger are the droplets and the hail, since they are moved through a short space. And the big droplets do not fall densely due to the same cause. Hail occurs less during the summer than during the spring and fall; more so, however, than during the winter, because the air during the summer is dryer. In the spring the air is still wet, and in the fall it is already becoming wet. Hail sometimes occurs, as has been said,[34] during the late summer due to the same cause.

Preheating the water contributes further to the speed of its solidification; for it cools faster. This is why many people, when they want to cool water quickly, first place it in the sun; and people in Pontus, when they make tents on the ice for fishing (for they fish by cutting through the ice), pour hot water on their stakes, because it solidifies faster. For they use ice like lead, so that the stakes are stable.

And rain that is being composed quickly becomes hot in regions and seasons that are warm. Around Arabia and Ethiopia, rains—and violent ones—occur during the summer and not during the winter, and many times during the same day due to the

34. 348ª1.

same reason. For [the vapor] cools quickly because of reciprocal replacement, which occurs because the region is intensely warm.

About rain, dew, snowfall, frost, and hail, then, due to what cause they occur, and what their nature is, let this much be said.

1.13
Rivers

Let us speak about the winds and all the wind-breaths, and further about the rivers and the sea, by first going through the puzzles about them on our own. For, just as on other subjects, we have heard nobody say anything about these matters that any random person could not say.

There are some[35] who claim that the wind is air (as it is called), when it is in movement and flowing, but that when it is composed, this same air again is cloud and rain, on the grounds that rain and wind are of the same nature, and that a wind is a movement of air. That is why some of those who wish to speak cleverly claim that all winds are a single wind, because it so happens that all moving air is one and the same thing, and [they think that], without being different at all, they seem to be different because of the places from which each of them happens to flow—making much the same claim as if one thought that all rivers are a single river. That is why ordinary people speak better without investigation than those who speak on the basis of an investigation of this sort. For if the rivers flowed from a single starting-point, and the winds for their part did likewise, then perhaps those who speak in this way would make some sense. But if the situation in the two cases is similar, their ingenious theory would clearly be a falsehood, since the proper thing to investigate is this: what a wind is, how it occurs, and what moves it; where do they draw their starting-point from and whether we really must suppose that wind flows, as it were, from a vessel, and whether it flows until the vessel is emptied, as if it were being released from wineskins, or as the painters paint them, discharging their starting-point from themselves. **349b1**

And some people think that the coming to be of rivers is the same; for the water that is drawn up by the sun, falls as rain again, gathers under the earth, and flows from a great hollow, either all the rivers from one hollow, or each from its own. And they claim that water does not come to be, but is collected from the winter storms into such reservoirs, and this is the coming to be of the multitude of rivers. That is also why their flow is always greater in the winter than in the summer, and why some rivers are perennial and others not. Rivers, whose collected waters, because of the size of their hollow, are big enough to hold out and not to be used up before the rains return in the winter, are persistent and perennial; but those whose reservoirs are

35. Hippocrates of Cos 64C2, Anaximander A24 DK.

smaller, because of the paucity of the water get dried out before the water from the heaven arrives, since their vessel gets empty.

And yet the fact is obvious, if one is willing to visualize a sort of receptacle and conceive what size [is necessary] for the continuous, daily flow of water. For the receptacle of all the water flowing for a year would exceed in magnitude the earth's bulk or would not fall much short of it.

But it is clear that many such receptacles occur in many places in the earth. Nonetheless, it is strange if one does not think that water comes to be from air by the same cause both above the earth and in the earth. So if the vaporizing air is composed into water because of the cold above the earth, we must think that this same process occurs as a result of the cold in the earth, and that it is not only the separating off of the water and its consequent flow that occurs in the earth, but also that it occurs continuously.

Further, we must think that the starting-point of the rivers' water, that which does not come to be but is already available day by day, is not like certain lakes that are separated off under the earth, as some say, but rather we must think that just as in the places above the earth small drops are composed and they in turn are composed with others and in the end the rainwater comes down in great quantity, so also in the earth at first they flow together from small [drops] and are like when the earth causes the starting-points of the rivers to gush forth together into one. And the facts themselves make this clear. For those who make irrigation systems conduct [the water] by
350^{a}1 conduits and channels, as if the earth were sweating from its heights. That is why the courses of rivers manifestly flow from the mountains too, and the most numerous and biggest of the rivers flow from the biggest mountains. Likewise too, the most numerous fountains border on mountains and high places. But in plains without rivers altogether few [fountains] occur. For the mountainous and high places, hanging over [lower areas] like a dense sponge, let the water percolate little by little and flow together in many places. For they both receive a great mass of falling water (for what is the difference whether the curve forms a hollow facing up or a convex facing down, since either way they will contain an equal mass of body?) and cool and aggregate the rising vapor back into water. That is why, as we said, the greatest of the rivers are seen to flow from the greatest mountains.

And this is clear if you look at the maps of the earth. For people draw up these [maps] in this way by learning from each [of their sources] things that those who report them happen not to have been eyewitnesses of. In Asia the most numerous and biggest rivers are seen to flow from the so-called Parnassus mountain. And this is agreed to be the biggest of all mountains toward the winter sunrise. For once one climbs over this mountain, the outer sea is visible, but its limit is not clear from inside. From this mountain there flow, besides other rivers, most notably the Bactrus, the Choaspes, and the Araxes rivers; the Tanais, being a part of this last one, is split off into lake Maeotis. And the Indus flows from it too, having the greatest flow of all rivers.

From the Caucasus many other rivers flow surpassing in number and magnitude, especially the Phasis. The Caucasus, for its part, is the largest of the mountains toward the summer sunrise, both in extent and in height. Indications of its height are that it is visible from what are called the "depths"[36] and to those sailing into the lake; again, the sun shines on its peaks during the night up till the third part both from the dawn and again from the nightfall. And [an indication] of its size is that it has[37] many places, where many tribes dwell and they claim that there are large lakes, but they claim that all these places are nonetheless visible as far as the highest peak.

And from Pyrene (this is the mountain toward the equinoctial sunset in Celtic territory) flow the Ister and the Tartessus rivers. The latter is outside the Pillars [of Heracles], but the Ister flows through the whole of Europe to the Black Sea. Among the other rivers, the greatest number flow northward from the Hercynian mountains. These mountains both in height and extent are the largest in that place. Under the Bear itself beyond remotest Scythia are the so-called Rhipae, concerning whose magnitude very fanciful accounts are reported: in any case, from here flow the most numerous and largest rivers after the Ister, as they claim. **$350^{b}1$**

Similarly, around Libya, some rivers flow from the Ethiopian mountains, like the Aegon and the Nyses, but the biggest of those that have names, that is, the so-called Chremetes, which flows into the outer sea, and the primary stream of the Nile, flow from the so-called Silver mountain.

Among those around the regions of Greece, the Achelous flows from Pindus, the Inachus from there, and the Strymon, Nessus and Hebrus, all three being from Scombrus; and there are many streams from Rhodope as well.

One might find that the other rivers flow likewise, but we mentioned these for the sake of evidence, since where rivers flow from marshes, the marshes happen to lie usually below mountains or places that gradually rise to a height.

We clearly must not think that the starting-points of rivers occur as if from delimited hollows. For neither the extent of the earth nor likewise that of the clouds would be practically sufficient, if the only thing that could flow is what [already] exists, and if it were not the case that some water departed and some came to be, but rather was always being dispensed from what exists. That [rivers] have springs under the mountains bears witness to the fact that a great deal of liquid flows together little by little and into a small space, which the place passes on, and in this manner the springs of rivers occur.

Nonetheless, it is in no way strange that there are such places that have, like lakes, an abundance of water, except that they are not big enough for this to occur,[38] any more than if one should suppose that the immediately visible springs of rivers are. For

36. $351^{a}11$.
37. Reading ἔχει.
38. I.e., to supply rivers.

pretty much the greatest number of rivers flow from fountains. So, it is like supposing that the former lakes and these visible springs are the entire body of water.

And the rivers that go underground make clear that there are such fissures and gaps in the earth. This occurs in many places in the earth; for example, in the Peloponnese most of them are found around Arcadia. And the cause of this is that, being mountainous, it does not have outlets from the hollows to the sea. For the places get filled up [with water] and do not have outlets, and so find passages to the depths, as the water descends from above and forces its way. In Greece, such things occur on a very small scale, but there is a lake below the Caucasus, which the inhabitants of the place call the "sea." For this, though many big rivers contribute to it, has no clear outflow, but issues forth below the earth where the Coraxi live, around the so-called depths of the Black Sea. These are a limitless depth of the sea. At any rate, no one has yet been able to drop a [sounding stone] and discover the bottom. In this place, distant from the land about three hundred stades, potable water comes up over a wide area, not continuously, but in three streams. And around Liguria a river[39] no smaller than the Rhone is swallowed up, and again issues forth in another place. As to the Rhone, it is a navigable river.

1.14
Land-Sea Exchange

It is not always the same places of the earth that are wet or dry; instead, they change according to the comings to be and failures of the rivers. That is why the areas surrounding the firm ground and the sea undergo change, and it is not the case that the same areas remain always and for all time land or sea; instead, the sea occurs where there was dry land, and where now there is sea, land will occur there again. However, we must think that these things come about according to some order and cycle. The starting-point and cause of these things is that the insides of the earth, just like the bodies of plants and animals, have a prime and an old age, except that [the plants and animals] do not turn out to be affected part by part, but the whole at the same time necessarily comes to its prime and wastes away. But with the earth this occurs part by part because of cooling and heating.

These things increase and decrease because of the sun and its revolution, and due to these things too, the parts of the earth take on different capacities, so that it is able to remain wet up to a certain time, then it dries out and grows old again. But other places revive and become wet part by part. And springs necessarily disappear as the places become drier, and when this happens, the rivers that were big first become small, and then in the end they dry up; and when the rivers relocate, disappearing from one place and correspondingly coming to be in others, the sea changes. For

39. Perhaps the Po.

where the sea has been pushed out by the rivers and has encroached [elsewhere], it necessarily produces dry land as it departs; and where it was full and silted up with its currents and dried out, there it must form a lake again.

But because all natural coming to be in the earth occurs gradually and over lengths of time very great in comparison to our lifespan, we do not notice them as they occur; and the extinction and destruction of whole nations occur before the change of terrestrial phenomena is remembered from beginning to end. The biggest and most rapid destructions occur in wars, but others occur through diseases and others again through famine; and when through the latter, some are big, while others are so gradual that even the migrations of such nations go unnoticed, because some people leave the lands, while others abide until the region is no longer able to feed any number of them. So, from the first departure to the last, it is likely that too long a period of time passes for anyone to remember, and [even] if a remnant [of the nation] still survives, they forget because of the length of time. And in the same way one must think that even the time fails to be noticed at which each nation first undertook a settlement in places that change and become dry from being marshy and wet. For the progress occurs here little by little over too great a time to remember who were first and when, and what state the place was in when they came.

This has happened with Egypt too. For this place clearly has become ever drier, and the whole region is clearly a deposit from the river Nile and, because little by little the marshes dried out and the nearby peoples came to settle, the length of time deprived them [of the awareness] of the starting-point. So all the mouths of the Nile, with the single exception of the one at Canopus, are artificial and not the product of the river. (And in ancient times Egypt was called "Thebes." Homer makes this clear,[40] though he is, so to speak, young in comparison to these changes. He makes mention of that place, as if Memphis did not yet exist at all or, at any rate, was not of its present size.) And it is likely that this would happen in this way; for the lower places were settled later than the upper ones. For the places nearer to the process of silting are necessarily marshy for a longer time, since lakes were always forming more in the furthest areas. And this area undergoes change and flourishes again; for the places dry out and come into a good condition, while those that were formerly temperate become worse as they dry out excessively.

This is what happened in Greece in the region of the Argives and Myceneans. For at the time of the Trojan War, Argos, due to its being marshy, was able to feed few people, while Mycenae was in a good condition (for which reason it was held in higher esteem), but now it is the opposite for the cause that was mentioned. For Mycenae has become infertile and altogether dry; but the land [of Argos] that was infertile because of the formation of lakes is now useful. So, we must suppose that the same thing happens in great places and whole regions, as has happened in this place, which is small.

40. *Iliad* 9.381.

Those who examine small things think that the cause of such affections is the change in the whole, because they suppose that the heaven is in the process of coming to be. That is why they claim that the sea too is coming to be smaller, on the grounds that it is getting drier, because more places are clearly undergoing this process now than previously. This is partly true and partly not true. For although a good number of places formerly wet are now dry land, the opposite is also certainly true. For if they look, they will find the sea making incursions [on the land] in many places. But one must not suppose that the cause of this is the coming to be of the cosmos. For it is ridiculous to suppose that the universe changes because of small and momentary changes, and without a doubt the bulk and magnitude of the earth is nothing in comparison to the whole heaven. On the contrary, we must think the cause of all these things to be a great winter and excessive rain in some great cycle that occurs at its appointed times, like the winter in the course of the annual seasons.

And this does not always occur in the same places, but like the so-called flood in the time of Deucalion. For this came to be mainly in Greek territory, and within Greece especially in old Hellas. This is the district around Dodona and the Achelous river. For this river has changed its course in many places. For the Selli used to live there and those who were once called "Graeci," but now are called "Hellenes." So whenever such excessive rains occur, one must think that the water lasts for a long time. And just as now the cause of some rivers being perennial and others not is, according to what some people claim, the size of the chasms under the earth and, according to what we claim, the size, density, and coldness of the lofty places (for these receive, contain, and produce the greatest amount of water; but where the range of overhanging mountains is small or porous and rocky and clayey, these places fail first), likewise it is necessary to think that the time, when such a transfer of liquid occurs, is such as to make the liquid in places more perennial. And in time these [latter] areas become more dried out,[41] while the others, the wet ones, become less dried, until the beginning of the same cycle returns. But since the whole must undergo some change—not however coming to be or passing away, since the universe endures—the same places, as we say, must not always be wetted by sea and river and again be dry.

The facts make this clear: we claim that the Egyptians are the oldest people and all their land manifestly came to be and is a product of a river. And this is clear to anyone who looks at the region itself. The facts concerning the Red Sea are also a sufficient proof. For one of the kings attempted to cut a channel through [to it] (for it would have been no small benefit for them to make the entire place navigable; and Sesotris is said to be the first one among the ancients to have tried), but he found the sea to be higher than the land. That is why he, on the earlier occasion, and Darius later, stopped digging, lest the course of the river be destroyed with the admixture of the sea. So it is clear that everything was once a single sea continuous with it. That is why the parts of Libya around Ammon also appear to be lower and hollower than we

41. Secluding γιγνόμενα.

would reasonably expect for low lands. For it is clear that when the silting came in, lakes and dry land came to be, but as time went on, the water, which was left behind in it and formed lakes, dried up and has now vanished. Further, the circumstances surrounding lake Maeotis have so advanced, because of the silting of the rivers, that only boats much smaller in size now sail into it for business than used to sixty years ago. From this it is easy to calculate that this lake, like the majority of lakes, is at first the work of the rivers, but in the end they all must become dry.

Further, the Bosporus always flows because of the new deposits being formed, and it is possible actually to see with our own eyes how it happens. For whenever the stream formed a bank on the Asian side, what was behind the bank came to be a lake, small at first, and then it would have dried up, and after this another bank came to be next to this, and a lake next to this. And this process continued without stop in this manner. And as this occurred many times, as time went on, something like a river must occur and in the end this too must become dry.

It is clear anyway, since time will not run out and the whole universe is eternal, that neither the Tanais nor the Nile has always flowed, but the place, from which they flow, was once dry. For their work has a limit, but time does not. Likewise, it is appropriate to make this claim in connection with the other rivers as well. But then, if indeed rivers come to be and pass away, and the same places on the earth are not always wet, the sea too must change accordingly. And as the sea retreats and advances continually, it is clear that it is not always the same parts of the whole earth that are sea and firm ground, but that everything changes with time.

We have now discussed why it is not always the same parts of the earth that are dry or navigable, and due to what cause these things happen; likewise, also why some rivers are perennial while others are not.

BOOK 2

2.1
Whether the Sea Has Springs

Let us speak about the sea, what its nature is and for what cause such a large quantity of water is saline, and again how it came to be in the first place.

The ancients[42] who busied themselves with stories about gods make it have springs, so that they might have starting-points and roots for earth and sea. For in this way they perhaps supposed that what they were describing was more high-flown and more dignified, as befits an important part of the universe; and they supposed that

42. Homer, *Iliad* 21.196, makes Ocean the source of rivers and springs. Hesiod, *Theogony* 282, 737–738 and 807–809 (the springs of Ocean and sea), 728 (the roots of the sea), 785–792 (the river Styx flowing underground into Ocean).

the whole of the rest of the heaven was composed around this place and for its sake, since they thought it was the most estimable thing and a starting-point.

Those wiser in human wisdom make it have a coming to be. For they claim[43] that at first the whole region around the earth was wet; then, as it was being dried out by the sun, part [of the water] vaporized and made the winds and the turnings of the sun and the moon, while part remained behind as the sea. That is why they think it is becoming even smaller, as it is drying up, and at some point will be completely dry in the end. But some of them claim that when the earth is heated by the sun, something like sweat occurs.[44] That is also why it is saline; for sweat is saline too. Others claim that the earth is the cause of the salinity: just as [water] becomes saline when strained through ashes, in the same way the sea is saline, because this sort of earth is mixed with it.[45]

At this point it is necessary to get a theoretical grasp on the basis of the facts that it is impossible for there to be springs of the sea. Among the terrestrial waters, some happen to flow, while others are stagnant. The flowing waters are invariably from springs (concerning springs, we said previously[46] that we need to think that a spring is not a starting-point the way in which something is dispensed from a vessel, but as a starting-point in the sense of the first point at which the water, continually coming to be and flowing together, meets in a single body). Among stagnant waters, on the other hand, some are collected in depressions, like the water of swamps and lakes, some big and some small in quantity, while others are spring water. These latter are all artificial, by which I mean what we call "well water." In all these cases the spring must be above the flow. That is why the former flow spontaneously, the fountains and the rivers, while these latter require additional labor and craftsmanship.

These, then, are the number and sorts of different waters. And since they have been distinguished in this way, it is impossible for the sea to have springs; for it can be of neither of these kinds; for it neither flows nor is it artificial, yet all water that comes from springs has one of these two features. Nor do we see any so large a quantity of stagnant water produced spontaneously from a spring.

Further, the seas that do not mix with one another in any place at all are
354ᵃ1 numerous—the Red Sea clearly has some small traffic with the sea outside the Pillars [of Heracles], but the Hyrcanian and Caspian Seas are separate from this sea and are inhabited all way around, so that the springs could not go unnoticed if they existed some place.

Also, the sea manifestly flows inside straits because the water ebbs and flows many times wherever the surrounding earth contracts the large sea into a small area. This is

43. Anaximander A27, Diogenes of Apollonia A17, Xenophanes A33.5–6, Anaxagoras A90, Democritus A100 = *Mete*. 356ᵇ10, Antiphon B32 DK.

46. 350ᵇ22–30.

not apparent in the broad extent of the sea, but where, because of the narrowness of the earth, the sea extends over a small place, it is necessary that the small oscillation in the open sea appear to be large there.

All the sea inside the Pillars of Heracles flows according to the concavity of the land and the size of the rivers. For the Maeotis flows into the Black Sea, and this flows into the Aegean. But this occurs less clearly in the case of the next open seas beyond these. But with the former it does happen because of the size of the [tributary] rivers (for more rivers flow into the Black Sea and lake Maeotis than into any other area many times their size) and because of their own shallowness. For the sea clearly gets continually deeper, the Black Sea being deeper than lake Maeotis, the Aegean than this, and the Sicilian sea than the Aegean. The Sardinian and Tyrrhenian seas are the deepest of all. The area outside the Pillars [of Heracles] is shallow due to the mud, and is windless since the sea is in a hollow. So just as the rivers clearly flow severally from the heights, so also with the whole earth, the greatest flows occur from the higher places in the north. The result is that some seas are not deep, due to their being poured out, while other seas beyond are deeper. There is a sign that the parts of the earth toward the north are higher in that many of the ancient meteorologists[47] were persuaded that the sun does not travel below the earth, but around the earth and this [northern] area, and that it disappears and creates night, because the earth is high toward the north.

Let this, then, be the sort and extent of our discussion of why there cannot be springs of the sea and of the cause due to which it is seen to flow in this way.

2.2
Views on the Origin of the Sea

We must now discuss the sea's coming to be, if it has come to be, and its taste, what the cause of its salinity and bitterness is. **354b1**

The cause that made our predecessors think that the sea is the starting-point and body of all waters is the following: it would seem to be reasonable, just as there is a concentrated mass and starting-point of the other elements because of their large amount, and parts of their mass undergo change and are mixed with the others—like the mass of fire in the upper places and the mass of air in the next place after fire, and the body of earth around which all these things clearly lie—so clearly, according to the same line of argument, it is also necessary to inquire about water. For there is no other evident body of this sort lying concentrated [in one place], as is the case with the other elements, except for the sea in its magnitude. For the water of the rivers is neither concentrated nor stagnant, but it appears on a daily basis as something

47. Anaximenes A7.6 DK.

that is continually coming to be. So it is from this puzzle that the sea seemed to be a starting-point of both wet things and of all water.

That is also why some claim[48] that the rivers flow not only into the sea, but out of it as well; for, when it is strained, the saline water becomes potable. But another puzzle is opposed to this belief: Why exactly is this composed water saline and not potable, if indeed it is the starting-point of all water? The cause will be at the same time the solution of this puzzle, and we must lay it down correctly as our primary supposition about the sea.

Since the water extends around the earth, just as the sphere of the air is around this, and that of the so-called fire around it (for this is the remotest of all, whether as the majority of people say it or as we do[49]), and since the sun travels as it does, and in consequence there is change and coming to be and passing away, the most delicate and sweetest part of the sea is drawn up on a daily basis, is disaggregated and carried as a vapor to the upper place, and there again being composed because of the cold, it is carried back down to the earth. And nature tends to do this continuously, as was said previously.[50]

This is why all our predecessors who supposed that the sun is nourished by liquid are ridiculous. Some, at any rate, make the claim that this is why it makes its turnings: **355[a]1** the same places are not always able to provide it with nourishment. Yet [the sun] either has to get [the nourishment] or be destroyed. For the fire that we can observe also lives only as long as it gets food, and liquid alone is food for fire. On the likely supposition that the liquid was drawn up and reached the sun, or that its rising was of the same sort as that of a flame coming to be, they made their conjecture about the sun in this way as well. But the cases are not similar. For flame occurs through the continuous change of wet and dry, and it is not nourished (for it does not remain as the same thing for—one might almost say—any time). But it is impossible that this should happen with the sun, since if it *is* nourished in the way they claim, it is clear that the sun is not just new every day, as Heraclitus claims,[51] but is always and continuously new.

Further, the drawing up of liquid by the sun is similar to water heated by fire. So, if the fire, which burns from underneath, is not nourished [by the water], neither is it a likely supposition that the sun is, not even if it heats up and vaporizes all of the water. And it is strange for them only to be worried about the sun and to overlook the preservation of the other heavenly bodies, being so great in number and magnitude. These people face the same absurdity as those who claim that at first the earth also was wet and that, since the cosmos surrounding the earth was heated by the sun, the air came to be and the whole heaven grew, and this [air] provided the winds and produced [the sun's] turnings. For we clearly see that the water drawn up always

48. Hippo B1, Xenophanes B30 DK.
49. 340[b]22, 341[b]14–18.
50. 347[a]5–6.
51. B6 DK, Xenophon A33.3 DK.

comes back down. Even if it does not return on a yearly basis and the same [amount] in each district, still it returns all that it has taken in some regular periods of time. Thus, the things above are not being nourished [by water], and it is not the case that some water remains air there after its coming to be [air], while the rest of water, after coming to be [air] passes away [and changes] back into water, but rather all likewise dissolves and is composed back into water.

All the potable and sweet water is carried up due to its lightness, and the saline remains behind because of its weight, but in a place not properly its own. For this is something one must think it also appropriate to be puzzled about (for it is unreasonable if there is no [proper] place for water as for the other elements), and its solution is as follows: the **$355^{b}1$** place we see the sea occupying is not the place of the sea, but rather the place of water. But it appears to be the place of the sea, because the saline water stays there because of its weight, while the sweet and potable is carried up because of its lightness, just as happens in the bodies of animals. For in these cases, though the food goes in sweet, the sediment of the wet food and its residue is clearly bitter and saline. For the sweet and potable material is drawn off by the innate heat and makes its way into the flesh and the other systems of parts, as each is naturally disposed.

Just as it is strange (indeed, the supposition would be incorrect) if someone does not consider the stomach as the place of the potable nourishment, because it disappears quickly, and instead considers it the place of the residue, because he sees this remaining behind, so the case is similar in these matters as well. For this is, as we say, the place of water, and that is why all the rivers and all the water that is coming to be flow into it. For they flow into the deepest hollow, and the sea occupies such a place on the earth. But one part is all carried up quickly because of the sun, while the other part is left behind for the stated[52] cause.

As for investigating the ancient puzzle as to why such a great mass of water appears nowhere (for the sea never gets any bigger though rivers countless and boundless in size flow into it every day), it is not at all strange that some people are puzzled. But when one examines it, the solution is not difficult to see. For the same amount of water poured out on a surface does not dry out in the same time as water in a concentrated mass; rather, [the drying times] differ so much that the latter could last the whole day, while the former could all disappear in the moment of a thought, just as if someone should spread a ladle full of water out on a big table. This is just what happens with the rivers: since the waters are always flowing continuously in a concentrated manner, the water that arrives at the vast and flat place [of the sea] dries out quickly and without a trace.

What is written in the *Phaedo*[53] concerning the rivers and the sea is impossible. For it is said that all are connected with each other through channels pierced under the earth and that the starting-point and spring of all waters is the so-called Tartarus,

52. $355^{a}32$–$^{b}6$.
53. 111c–113c.

356a1 a large quantity of water around the middle; and from this issue forth all the flowing and the non-flowing waters. And this first water, a starting-point, produced a flow in each of the streams by its endless oscillation; for it does not have a stable seat, but is always whirling around the middle. And as it moves up and down it produces the flow of the rivers. Some of it forms lakes in many places, for example, our [Mediterranean] sea, but they all lead back around in a circle to the starting-point, whence they began to flow, many through the same region, but others flow back opposite to the place of their efflux, for example, if they started to flow from below, they come back in from above. The descent of the water is as far as the center; for all the rest of the spatial movement is then uphill. And the water gets flavors and colors through whatever sort of earth the rivers happen to flow.

On this account, it turns out, the rivers do not always flow in the same direction; for since they flow toward the middle whence they flowed forth, they will flow no more down than up, but rather to whichever side Tartarus inclines in its swell. And yet, if this occurs, the proverbial "rivers flowing uphill" would occur—which is precisely what is impossible.

Again, where will the water that is produced and carried up again come from? For it is necessary to destroy its whole mass, if the equilibrium is to be always preserved. For however much flows out, flows back toward the starting-point.

And yet all the rivers that do not end in each other clearly do end in the sea. No river ends in the earth, but if it disappears, it resurfaces again; and those rivers that flow far through the hollows [of the earth] become large; for they receive the flows of many rivers by absorbing their courses by their positions and length; and this is just the reason why the Ister and the Nile are the biggest of the rivers debouching into this sea. And where springs are concerned, different people claim different causes for each of the rivers, because many rivers issue forth into the same river. In fact, it is clearly impossible for all of this to happen, especially on the supposition that the sea has its starting-point from there [that is, from Tartarus].

Let this much, then, be our discussion [showing] that this is the place of [sweet] water and not of the sea, why potable water cannot be seen except when flowing, while the other part remains behind, and why the sea is the terminus of water rather
356b1 than its starting-point, as with the residue of all food in animals' bodies, and most of all that of the wet residue.

2.3
Salinity of the Sea

Let us speak about [the sea's] salinity, and whether the sea is always the same, or whether it did not exist or will not exist but disappear; for in fact this is what some people think.

Everyone seems to agree that the sea came to be, if indeed they suppose the whole cosmos came to be; for they make the sea come to be at the same time. So clearly, if the universe is in fact eternal, one must suppose the same about the sea too.

But to suppose that its volume is diminishing, as Democritus claims,[54] and that in the end it will disappear—this seems no different from believing the tales of Aesop. For Aesop told the story that Charybdis swallowed down [the seawater] twice: the first time she made the mountains appear, and the second time she made the islands appear, and when she swallows down the last time, she will make everything altogether dry. Telling this sort of story was fitting for Aesop who was angry with the ferryman, but is less so for those who are seeking the truth. For it is clear that the cause due to which the sea remained at the beginning, whether because of its heaviness, as some of them do claim (for the cause is obvious to see), or because of something else, is the one due to which it must persist for the rest of time too. They should say either that not even the water drawn up by the sun will come back down, or if it does come back down, that the sea must either remain behind always or for as long as the [fresh water comes back down]; and that again the potable water must first be drawn back up. The result is that the sea never gets dried out; for [before that happens] the water that ascended will descend again into the same sea. It makes no difference whether we say this happens once or many times.

If one supposes that the sun stops its spatial movement, what will be the drying agent? If, however, it is allowed to have a circular movement, whenever it approaches the earth it will draw up the potable water, as we said, and whenever it withdraws, it will release it again. But they grasped their conception about the sea from the fact that many places appear drier now than previously. We stated[55] the cause of this: this affection arises because excess water is produced over a certain period of time, and not because of the coming to be of the whole universe and its parts; and the opposite effect will occur in its turn. And when this occurs, [the area] will be dried out again. This must always proceed in a cycle in this way; for it is more reasonable to suppose this than to make the whole universe change because of these things.

Our argument has been drawn out longer than these issues warrant. But where salinity is concerned, it is impossible for those, who have made the sea come to be on one single occasion, as well as for those who make it come to be at all, to make it saline. For whether it is the remnant of all the liquid around the earth that has been drawn up by the sun that came to be the sea, or such a strong flavor were present in so large and sweet a body of water because of the sort of earth mixed in with it, nonetheless, since the vaporized water returns and its amount, at any rate, is equal, it is necessary that [the sea was saline] at the beginning as well; otherwise, if it was not saline at the beginning, it should not be saline later either. But if it was saline straight from the start, one should say what the cause is, and also why it does not undergo

54. A99a, 100 DK.
55. 352^{a}25.

the same process now, if it was drawn up then too. Further, for those who attribute the cause of salinity to the earth that is mixed in (for they claim that earth has many flavors, making the sea saline because of the mixture, when it is carried down by the rivers), it is strange that the rivers are not saline as well. For how is it possible for the mixture of this sort of earth to be so obvious in a large amount of water, but not in each of the rivers? For it is clear that the sea consists entirely in river water; for it differs from rivers in nothing else than in being saline, and this arrives by those river courses to the place into which they gather and flow.

It is likewise ridiculous, if someone says that the sea is the sweat of the earth and thinks he has said anything clear, as Empedocles did.[56] In so speaking, he has perhaps come up to the standards of poetry (for metaphor is a feature of poetry), but for knowledge of nature it is not sufficient. For it is not clear here either how the sweat becomes saline from the sweet water we drink, whether it is just by the departure of something, like the sweetest part, or by something being mixed in, just as with waters that have been filtered through cinders. But the cause appears to be the same in the case of the residue that is collected into the bladder; for in fact this residue becomes bitter and saline, although what we drink—that is, the wet component in our food—
357b1 is sweet. So if, like the water that is filtered through ash, urine becomes bitter, and that, because it carries with it the same sort of capacity that we see precipitating in vessels as salt scum, and because sweat is excreted from the flesh together with this capacity (as when some liquid, as it leaves, rinses such a thing out of the body), it is clear that in the case of the sea too the cause of the salinity is the material from the earth that is mixed with the wet.

This sort of material is produced in the body as a sediment of food due to the lack of concoction. But we must say how it came to be available in the earth: in general, how can such a large amount of water be excreted as the earth dries out and gets warm? For it could only be a small fraction of what is left in the earth. Again, why does the earth, whether a smaller or greater amount, not sweat now too, whenever it happens to be drying out? {For the liquid—that is, the sweat—becomes bitter.}[57] For if in fact it did then, it should do so now as well. But this does not appear to happen; rather, when it is dry, it then becomes wet; but when it is wet, it undergoes no such thing. So how is it possible, at the time of the first coming to be, for the earth, when it was wet, to have sweated as it was drying out? On the contrary, it is more likely, as some claim, that the sea is the remnant after most of the liquid has departed and has risen because of the sun. But it is impossible for it to sweat when it is wet.

The stated causes of salinity seem to be beyond the reach of reason. But let us say [what we think], assuming the same starting-point we did previously.[58] For since it is

56. A66, B55 DK.
57. This seems out of place in the argument.
58. 341b6–13.

laid down that there is a twofold exhalation, one wet and the other dry, it is clear that we must consider the latter as the starting-point of such things.

And, in particular, [let us speak] about what needs first to be puzzled out: whether the sea always persists because it has numerically the same parts or because its parts always change in form and in quantity, just like the air and the potable water and fire do (for each of these is always in the process of becoming, though the form of each of their masses remains constant, just as the stream of flowing waters and of flame). The following, then, is clear and convincing, that it is impossible for there not to be the same account concerning all these things. They differ in the speed and slowness of their change, but in all cases there is passing away and coming to be. However, they **358ᵃ1** all undergo these changes in an orderly manner.

Since this is the case, we must try to give our account of the cause of salinity. It is certainly evident through many signs that this sort of flavor is produced due to a mixture of something. For in [animals'] bodies, what is least concocted is saline and bitter, just as we said previously;[59] for the residue of wet food is least concocted. Sediment is always of this sort, but the sediment in the bladder is most so (a sign of this is that it is the finest-grained material; for all things that are being naturally concocted get composed). And next [to urine in being unconcocted] is sweat. The same body is excreted together [with the liquid] in these two cases, and this body produces this flavor. It is similar in things that are burned; for what the heat does not take control of becomes residue in [animals'] bodies and cinders in things that are burned. That is why some claim that the sea has come to be from thoroughly burned earth. It is strange to state the matter so, but that it comes to be from earth of this sort is true. For just as in [the animal processes that] we have discussed, so also in the whole, we must suppose that from things that naturally grow and that are continually coming to be by nature, just as from things that are burned, the remnant is earth of this sort and especially all the exhalation in the dry [earth]. For this [exhalation] is what provides the great quantity [necessary to salinate the sea]. And since, as we said,[60] the vaporous and the dry exhalations are mixed, whenever they are composed into clouds and water, some amount of this [dry] capacity must be continually enclosed, and carried back down with it when it rains. This is continually coming to be according to some regular order, to the extent that it is possible for things here [in the sublunary world] to have a share of order. We have now discussed where the salinity in water comes from.

And because of this, rains accompanied by the south wind and the first rains of fall are more brackish; for the south wind, both because of its extent and its wind,[61] makes for a very warm wind. It blows from dry, hot places, so that it has little vapor. That is why it is hot; for even if it is not so and is cold at the place from which it

59. 357ᵇ8–9.
60. 344ᵇ20–26.
61. The text here is uncertain.

starts to blow, nonetheless, as it moves along, it is hot because there is a lot of dry exhalation being enclosed with it from the nearby places. But the north wind, since it is from wet places, is vaporous. That is why it is cold. And by pushing away [the vapor] it causes clear skies here, but in the opposite [areas] it brings rain. Similarly, the south wind also causes clear skies for the areas around Libya. In the water that is being carried down, then, a lot of such [dry exhalation] is accumulated, and the rains of fall are brackish; for it is necessary for the heaviest material to be carried first. So rains, in which there is a large amount of such earth, tend downward most quickly. And the sea is hot, at any rate, because of this; for everything that is burned potentially has heat in it. One can see this in ash and cinders and the dry and wet excretions of animals: the animals that have the hottest stomach, at any rate, have the hottest excretion.

Due to this cause, then, [the sea] is continually becoming more brackish, but some part of it is continually carried up with the sweet water. (But it is less, the less salinity and brackishness there is than sweet in the rain. That is why as a whole they practically equal out.) And having made a test of it, let us say that it becomes potable by being vaporized and that whenever it is composed again, the vaporized material is not aggregated into seawater. And other things undergo the same process. For wine and all the other juices, whenever they have been vaporized and composed back into liquid, become water. For the other liquids are affections of water due to some mixture, and whatever is mixed in, makes the flavor of the juice to be such-and-such. But we should make our investigation into these things on other more appropriate occasions.[62] For now, let us say this much, that since the sea always exists, some part is continually being drawn up and becomes potable, and comes down from above in the rain having become something else, not that which was drawn up. Due to its weight it is situated underneath the potable water. And that is why the sea, like the rivers, does not fail, other than locally (for this necessarily happens equally in both domains); nor do the parts always remain the same, neither of earth nor of sea, except in terms of the entire mass. For we must also suppose the same sort of thing concerning the earth; for the one part [of the earthen material] goes up, another part comes back down with [the rain], and what stays on top and what is going back down exchange places.

That salinity resides in the mixture of something is clear not only from what has been said but also if one fashions a wax vessel and places it in the sea, having tied off its mouth in such a way that no seawater might pour in; for the water that comes in through the waxen sides becomes potable. For the earthen material—that is, what produces salinity due to the mixture—is segregated out just as through a sieve; for this is the cause of the heaviness (for saline water weighs more than potable) as well as of the viscosity. The viscosity is so much greater, that ships of the same weight in cargo almost sink in rivers, though on the sea they are moderately buoyant and

62. Perhaps in the lost *On Flavors*.

seaworthy. That is why, indeed, some who have freighted their ships in rivers have been damaged because of their ignorance. The fact that the mass is more viscous is a proof of what is mixed in: if one makes water excessively saline by mixing in salt, eggs float upon it, even if they are full. For the water becomes pretty much like mud, such a large quantity of material does the sea contain. People do the same thing concerning pickling as well.

And if there is a lake in Palestine, as some storytellers say, such that if you tie up and throw a man or a beast of burden into it, they float and do not sink under the water, this would be a proof for what has been said. For they say that the lake is so bitter and saline that there are no fish in it and that you can wash your clothes, if you just dip them in and shake them out.

All the following are signs of what has been said, that it is a certain body that makes water saline and the thing it contains is earthen. For in Chaonia there is a fountain of rather brackish water and it flows out into the neighboring river, which is sweet but has no fish. For, as the locals tell the story, when Heracles, coming with his cows from Erytheia, gave them the power, they chose the salt in exchange for the fish, which they got from the fountain. For they boil off some portion of this water, and lay it aside, and it cools and, when the liquid has vaporized off with the heat, it becomes salt crystals which are not coarse but loose and delicate like snow. It is weaker in its capacity than other sorts of salt, and it seasons dishes only when more is added, and is not as white in color. A similar sort of thing occurs in Umbria; for there is a place where reeds and rushes have grown. They burn them, throw **359b1** the cinders into water, and boil them. When some part of the water is left, this is cooled and becomes a mass of salt.

As regards the streams of rivers or fountains that are saline, we must think that the greatest number were hot at some time, then the starting-point of fire was extinguished and there still remains something like the ash and cinders of the earth they are filtered through. And in many places, there are fountains and streams of rivers that have all manner of flavors, and the cause of all of them is to be attributed to the capacity of fire that dwells or supervenes in them. For when earth is burned, it takes on various forms and appearances of flavors varying by the more and the less; for it becomes full of astringent material and ash and other such capacities, through which the sweet water is filtered and changes, and some becomes acid, like in Sicania in Sicily; for the earth there is acid-salty, and they use it like vinegar for some of their food. And there is a fountain of sour water in Lyncus, and a bitter one in Scythia. And its flow makes the whole river into which it flows bitter. The differences of these things are clear from the following: what sort of flavors come to be from what sort of blends. We have discussed these things separately elsewhere.[63]

We have now pretty much completed the major part of the discussion concerning water and the sea, due to what causes they exist always and continuously, and how

63. *Sens.* 4.

they change, and what their nature is, and again what affections they happen to produce and undergo in accord with nature.

2.4
The Material Cause of Winds

Let us discuss the winds, assuming the starting-point we have already mentioned previously. For we claim[64] that there are two forms of exhalation, the wet and the dry. The former is called "vapor," and the latter, taken as a whole, has no name, but we must use a name appropriate to a part, and call the whole something like "smoke." The wet does not exist without the dry, nor the dry without the wet, but they all get their names according to the excess [of one factor over the other].

The sun travels in a circle, and so, when it approaches, it draws up liquid by means of its heat, and when it gets further away, the vapor that has been drawn up **360ᵃ1** is composed again into water because of the cooling (that is why rain occurs more during the winter and more at night than during the day; but this does not appear to be the case, because we do not notice the nighttime rains as much as the daytime rains). So, all this water descends and is distributed over the earth, and there exists in the earth a lot of fire and a lot of heat, and the sun draws not just the liquid that rests on the surface of the earth, but also dries out the earth itself by heating it. Since the exhalation is twofold, as we have said,[65] the vaporous and the smoky, it is necessary that both occur. Among these, the exhalation that has the greater amount of liquid is the starting-point of the rainwater, as was said previously,[66] while the dry is the starting-point and nature of all the winds. And the facts themselves make clear that these things must occur in this way. For it is necessary for the exhalation to differ, and it is not just possible but necessary for the sun and the heat in the earth to produce these things.

And since the form of each is distinct, it is clear that they differ, and that the nature of wind and the nature of rainwater are not the same, as some people say.[67] For they claim that the same air, when it is moving, is wind, but when it gets composed again, is water. {As we have said[68] in our accounts prior to these, air comes to be from these [exhalations]. For vapor is wet and cold (because it is wet, it is easy to delimit; and because it arises from water, it is cold in its proper nature, just like unheated water); smoke is hot and dry. So just as with tokens, the air would be composed as wet and hot.}[69] For it is strange, if this air, which is pervasive around us all, becomes

64. 341ᵇ5–12.
65. 341ᵇ5–12.
66. 346ᵇ20–347ᵃ12.
67. Anaximenes A7.7, implied by Metrodorus of Chios A18 DK.
68. Perhaps 340ᵇ24–28.
69. This should be rejected as spurious.

a wind just because it moves, and is the wind it is, just because it happens to move from a certain direction, and not, as we supposed with the rivers that they are not just water flowing in any random way—not even if they are of significant quantity—but rather their flow must be from a spring. For this is the way it is with the winds as well; for a great quantity of air, without starting-point or source, may be moved by some great fall.

And what happens bears witness to what has been said. For because the exhalation continuously occurs, more or less forcefully, in greater or smaller quantities, the clouds and winds continuously occur, each according to its natural season; and **360ᵇ1** because sometimes the vaporous exhalation, sometimes the dry and smoky, is many times as big as the other, some years become very rainy and wet, and some are breezy and droughty. Sometimes, then, it happens that both extensive droughts and numerous heavy rains occur at the same time over a continuous district. And sometimes this happens in parts of districts; for often a whole district round about gets its seasonal rains or even more, while in some one part of it there is drought. Sometimes the opposite happens, and the whole district all around has just moderate rain or is even rather droughty, while one part of it gets a plentiful amount of rain. The cause is that for the most part the same affection is likely to extend over a wider district, because neighboring areas share pretty much the same position relative to the sun, unless they have some special difference.

Nonetheless, sometimes in some particular part the dry exhalation becomes greater, and in another the vaporous one; and sometimes the opposite. The cause of this is that each part changes over to the exhalation of the next district—for example, the dry exhalation flows in its proper district, while the wet one flows to the neighboring district or was pushed off into one of the remote areas by the winds. And sometimes, while the latter [wet] exhalation remained, the opposite exhalation did the same thing [as the wet in the previous example]. And this often occurs, as in the [living] body, if the upper stomach is dry, that the lower stomach is in the opposite condition, and when the lower stomach is dry, the upper stomach is wet and cold; it is in the same way that the exhalations undergo reciprocal exchange and change their places.

And again, after the rains, a wind usually occurs in those areas where the rains happen to have occurred as well; and the winds cease, when the rain has occurred. For these things must happen because of the starting-points we have discussed; for after it has rained, the earth dries out through the heat that is in it and the heat from above, and emits exhalations. This is the body of the wind. And whenever this sort of segregation occurs and the winds prevail, then they stop because the hot material is constantly segregated out and carried up to the upper place, and the vapor gets cooled, composed, and becomes water. And whenever the clouds are pushed together into the same place and the cold gets confined in them, water comes to be and cools **361ª1** down the dry exhalation. So when rains occur, they make the winds cease; and when the winds cease, rain occurs due to these causes.

Again, the cause is the same for most winds coming to be from the Arctic and the south. For most of the winds are north or south; for these are the only places that the sun does not reach; instead, it [just] approaches them and withdraws from them, but it always travels toward the settings and the risings. That is why the clouds are composed in the places on either side and the wet exhalation occurs when the sun advances, but when it withdraws to the opposite place, then rains and storms occur. Because of the spatial movement of the sun toward and away from the tropics, then, summer and winter occur, and the water is drawn up and [rain] is produced again. Since the greatest amount of water falls in those places toward which and away from which the sun turns, that is, the places facing the Arctic and the south, and since it is necessary that the greatest amount of exhalation occurs where the earth receives the greatest amount of water (in much the same way as smoke is produced from green wood), and this exhalation is a wind, it would be reasonable that the greatest and most dominant of the winds arise from these places. The winds from the Arctic are called "Boreae," and the winds from the south "Notoi."

As to their spatial movement, it is oblique, since they blow around the earth, though the exhalation naturally moves straight up, because the whole circle of the air follows the spatial movement [of the heavens]. That is why one might also be puzzled about which of two sources the starting-point of the winds is from, from above or from below. For the movement is from above, even before the wind blows, and the air makes it obvious, if there is cloud or mist; for it shows that the starting-point of the wind is moving before the wind has perceptibly arrived, indicating that they have their starting-point from above. And since a wind is a mass of dry exhalation from the earth moving around the earth, it is clear that the starting-point of the movement is from above, and the starting-point of the material and coming to be is from below. For the cause originates from the place where the ascending material will flow; for the spatial movement of the things more remote from the earth are in control. But at the same time [the exhalation] rises straight up from below, and what is close always has greater strength, and the starting-point of coming to be clearly is from the earth.

And it is clear also on the basis of the facts that the winds occur from many
361b1 exhalations coming together little by little, just like the starting-points of rivers, when the earth is damp. For they are all weakest at the source from which they blow, but as they proceed further, they blow vigorously. Again, the areas around the Arctic are calm and windless in the winter, that is, in that area itself. But what blows little by little and is hardly noticed as it goes forth, becomes in due course a vigorous wind.

What the nature of the wind is, and how it occurs, and again concerning droughts and rains, and due to what cause the winds cease and occur after rains, and why the north and the south winds are the most numerous, has been discussed, and in addition to these things, their spatial movement as well.

2.5
The Efficient Cause of Winds

The sun both makes the winds cease and spurs them on. When the exhalations are weak and meager, the sun with its greater heat causes the heat in the exhalation, being smaller, to fade away and disperse. Again, it first dries out the earth itself, before a concentrated segregation occurs: just as if a small amount of fuel falls upon a large fire, it is often burned up before it produces smoke. Due to these causes the sun makes the winds cease and prevents them from coming to be in the first place: it makes them cease by causing them to fade away; but it also prevents them from coming to be by quickly drying out [the earth]. That is why a calm occurs there especially around the time of the rising of Orion and lasts until the Etesian winds and their Forerunners. In general, calms occur from two causes: either because of the cold the exhalation is extinguished, for example, whenever a sharp frost occurs; or because [the exhalation] is caused to fade away by the stifling heat. And the greatest number of calm spells occur in the intermediate seasons, either because the exhalations have not yet started or because the exhalation has already issued forth and another one is not yet flowing in turn. Orion seems to be hard to discern and difficult [as a weather sign], both when it sets and when it rises, because its setting and rising occur at the change of the season, summer or winter, and because it occurs over a number of days due to the large size of the heavenly body.[70] And the changes in all [the winds] are confused due to this indeterminacy.

The Etesian winds blow after the solstice and the rising of the Dog Star,[71] not at the time when the sun is closest, nor when it is far off. They blow during the day but cease at night. The cause is that the sun is close and dries [the earth] before the **362^{a}1** exhalation is produced. But when it retreats a little, the heat of [the sun] becomes well balanced,[72] so that the solidified water melts and, as the earth is dried out by its own heat and by that of the sun, starts to produce smoke, as it were, and exhalations. But during the night they abate, because the solidified water ceases to melt due to the coldness of the nights. What is solidified does not produce exhalation, nor does what has no dry component; instead, dry material, when it has liquid and is heated, generates exhalation.

Some people puzzle about why, while steady north winds, which we call the "Etesian winds," occur after the summer solstice, no similar south winds occur after the winter solstice. This state of affairs, however, is not unreasonable. For the so-called Clear South winds occur at the opposite season, though they are not as steady. And the fact that they elude our notice spurs us to investigate. The cause is that the north wind blows from the places under the Bear, places that are full of a great deal of water

70. I.e., the constellation.
71. In July.
72. Secluding ἡ ἀναθυμίασις καὶ.

and snow. And it is when they are melted by the sun, more after the summer solstice than during it, that the Etesian winds blow. For the stifling heat occurs in this way too, not when [the sun] is closest to the Bear, but when it has had more time for warming, but is still close. Likewise, after the winter solstice the Bird winds blow. For these are weak Etesian winds. They blow less and blow later than the Etesian winds. For they begin to blow on the seventieth day [after the winter solstice], because the sun is far off and exercises less power. They do not blow as continuously, because some are at that time separated [from their point of origin] in a superficial and weak manner, while others that are more solidified need more heat. That is why they blow intermittently, until the Etesian winds blow at the summer solstice again, since a wind always has a tendency to blow from there with the utmost steadiness.

The south wind blows from the summer tropic and not from the other Bear [Fig. 1].[73] For there are two sections of the habitable earth, the one facing the upper pole, where we live, and the other facing the other pole, toward the south. They are like drums [Fig. 2]; for the lines drawn from the center of the earth cut off this sort of shape, and they make two cones, the one having as its base the tropic, the other having the ever-visible circle, and the apex being at the middle of the earth. In the same way, two other cones make sections of the earth toward the pole below. These [two sections] alone can be inhabited, and not those beyond the tropics (for [that region could have] no shadow fall toward the north, and as it is, regions become uninhabitable before the shadow disappears or shifts toward the south), nor the areas under the Bear because of cold. (And the Crown too travels in this place; for it is clearly apparent to us over our heads, whenever it is on the meridian.)

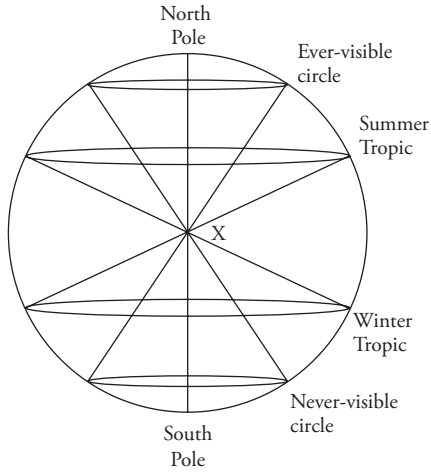

Fig. 1

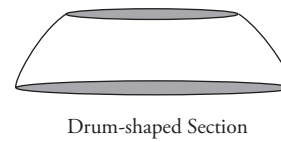

Fig. 2

73. I.e., the Antarctic region.

That is why the way [mapmakers] draft the maps of the earth is ridiculous; for they draw the inhabited world as circular, but this is impossible both on the basis of what appears to be so and on the basis of argument. For argument shows that it is bounded in breadth, but it can connect up in a circle on the basis of climate: for the heat and the cold do not run to extremes along the length, but rather along the breadth, so that unless the extent of the sea blocks it somewhere, [the length] can all be traversed on foot. The same can be shown also according to what appears to be so from sailing voyages and journeys; for the length [of the inhabitable world] is much greater than the breadth. For the magnitude [of the distance] from the Pillars of Heracles to India in comparison to that from Ethiopia to Maeotis and the places at the extremes of Scythia is greater than five to three, if one[74] calculates the sailing voyages and the itineraries, to the extent that it is possible to grasp the exactness of such things. And yet we know the inhabited world along its breadth up to the uninhabited parts: for habitation ceases on the one side because of the cold, and on the other because of the warmth. And because of the sea the places beyond India and the Pillars of Heracles do not seem to join together the entire inhabited land in such a manner as to be continuous.

Since it is necessary for there to be some place facing the other pole, just like the one we inhabit faces our pole, it is clear that everything else, as well as the position of the winds, is correspondingly arranged. So that just as there is a Boreas wind here, so they too have some such wind blowing from their Bear. This wind simply cannot make its way here, since not even our Boreas is found in the entirety of our inhabited world. For the northern wind is like a land wind. But because this inhabited district of ours lies toward the Bear, most winds blow from the north. Nonetheless, here too it fails and is not able to travel far, since the east and west winds always blow continuously in succession around the southern sea beyond Libya, like here the northern and the southern winds blow.

It is clear that the south wind is not the one blowing from the other pole. And since it is neither that one, nor the one from the winter tropic (for in that case, there would have to be another one from the summer tropic: for this is the way it will produce correspondence; but as it is, there is none, since there is clearly only one blowing from those places), it is necessary that the south wind be the wind blowing from the thoroughly burned place. That place, because of its proximity to the sun, does not have water and pasturage,[75] which will produce Etesian winds, due to the solidification. But because that place is much larger and more open, the south wind is greater and larger and warmer than the north, and travels a greater distance over here than this one there.

What the cause is, then, of these winds and how they relate to one another, has been discussed.

74. Reading ἐάν τις τούς τε.

75. "Pasturage" should perhaps be emended to "snow."

2.6
Catalog of the Winds

Let us now discuss the winds' positions, which winds are opposed to which, which sorts can blow at the same time and which ones cannot; and further, what winds happen to exist and how many they are; and in addition, the other affections that happen not to have been discussed in the particular problems.

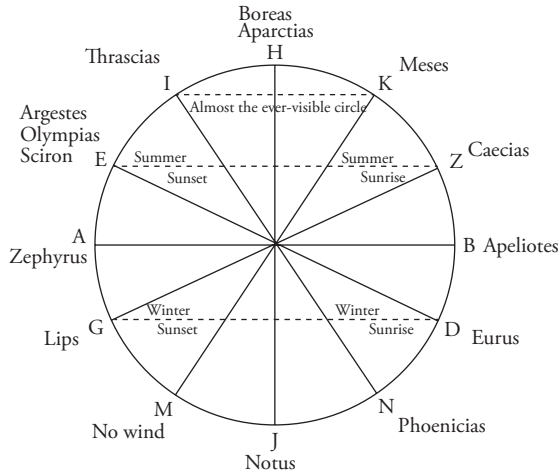

Fig. 3

It is necessary at the same time to consider the arguments about their positions on the basis of the diagram. We have drawn the circle of the horizon in order to be clearer, and that is why [our figure] is round. But we need to consider it[76] to be just the one section, the one that is inhabited by us: for we can divide up the other one in the same manner. Let us first lay down that spatial opposites are the ones most distant in space, just as formal opposites are those most distant in form. And those spatially most distant are those that lie on the diameter facing one another.

So let A be the equinoctial sunset, and let the place opposite to it, B, be the **363b1** equinoctial sunrise [Fig. 3]. And let there be another diameter cutting this one at a right angle, and let its point H be the Bear; and the opposite point facing it, J, the midday [that is, south]. And [let] Z be the summer sunrise, and E be the summer sunset, and D be the winter sunrise, and G be the winter sunset. And let a diameter be drawn from Z to G and from D to E. So, since those that are most distant in place are opposite in place, and points on the diameter are the most distant, it is necessary for these winds, which are on the diameters, to be opposites to each other.

76. Reading αὐτὸν.

The winds are named according to the position of their locations as follows: Zephyrus is from A, since this is the equinoctial sunset. Opposite to this is Apeliotes from B, since this is the equinoctial sunrise. Boreas—that is, Aparctias—is from H, since the Bear is here. And opposite to this is Notus from J, since it is midday,[77] from which it blows, and J is opposed to H, since they are on a diameter. Caecias is from Z, since this is the summer sunrise. The opposite is not the wind that blows from E, but the one from G, Lips, since this is from the winter sunset, and is opposite to it (for it lies on the diameter). Eurus is from D, since it blows from the winter sunrise, a neighbor to Notus. For this reason one often says that the "Euronoti" winds blow. Opposite to this is not Lips from G, but the wind from E, which some people call "Argestes," and others call "Olympias," and others again "Sciron." For this wind blows from the summer sunset, and alone lies on the diameter to it [that is, Eurus].

Those are the winds that lie on a diameter and their opposites. But there are others that do not have opposite winds. For the wind from I, which they call "Thrascias," [does not have an opposite,] since it is in between Argestes and Aparctias. And the wind from K, which they call "Meses," [does not have an opposite,] since it is in between Caecias and Aparctias. The diameter IK tends toward the ever-visible circle, but is not exactly so. There are no opposites to these winds, neither to the Meses (for there would be one that blows from the point M; for this is on the diameter), nor to I, Thrascias (for it would blow from N. For this point is on the diameter, unless we count the wind that blows from it for a short distance, which those who live around this place call the "Phoenicias").

These are the most dominant and distinct winds and they are arranged in this manner. The cause of there being more winds that arise from places toward the Bear than from those toward the south is that the inhabited world is oriented toward that place; and, because much more rain and snow are pushed into this part, because the other place is under the sun and its spatial movement, and when they are melted into the earth and heated by the sun and the earth, the exhalation is necessarily produced, which is greater and extends over a wider place due to this cause.

Among the winds that were mentioned, Aparctias is northern in the strictest sense, and then Thrascias and Meses. Caecias is shared between east and north. Southern winds are both the genuine one [Notus] which blows from the south, and Lips. And the eastern winds are the ones from the equinoctial sunrise and Eurus. The Phoenicias is common [to east and south]. The western winds are the genuine one [Zephyrus] and the so-called Argestes. Generally speaking, some of these are called "northern," others are called "southern." The western winds are added to the northern (for they are colder, because they blow from the sunset), and eastern winds are added to the southern (for they are hotter because they blow from the sunrise). So, since the winds are distinguished by cold and hot and warm, people give them their names accordingly. The ones from the dawn are hotter than the ones from the sunset, because the ones from the sunrise are under the sun for

77. I.e., south.

a longer time: as for the winds from the sunset, the sun leaves them faster and approaches the place later.

Since the winds are arranged in this way, it is clearly impossible for the opposite ones to blow at the same time (for they are on the diameter, and one of them will be forced to stop). But nothing prevents winds that are not positioned this way, for example Z and D, [from blowing at the same time]. That is why sometimes two winds may blow together toward the same point and be both favorable, though not from the same point nor with the same wind. Opposite winds blow especially in opposite seasons—for example, around the spring equinox, Caecias and in general the winds beyond the summer tropic, while around the fall equinox, Lips; and around the summer solstice, Zephyrus blows, while around the winter solstice Eurus. Aparctias, Thrascias, and Argestes are the winds that especially confront the others and stop them. For because their impulse is very close by, it is most of all these winds that blow numerous and strong. That is why these winds produce the clearest skies. They stop the other winds, because they blow from very close by and force their way, and because they blow away the clouds that are being composed, they produce a clear sky, if they do not happen to be at the same time too cold. [If they are too cold,] they do not produce a clear sky. If they are colder than they are big, they solidify the clouds before they push them off. Caecias is not associated with clear skies, because it bends back upon itself. So the saying goes, "drawing to himself as Caecias [does] a cloud."

The veering around [of the winds] occurs when they are made to cease by those [winds] that are next in the movement of the sun, because what is next to the starting-point is most susceptible to movement, and the starting-point of the winds moves as the sun does.

Opposite winds produce either the same or the opposite [effect]. For example, Lips and Caecias, which some call "Hellespontias," are wet;[78] but Argestes and Eurus are dry. This latter wind starts out dry but ends up wet. Meses and Aparctias are especially associated with snow; for they are the coldest winds. Aparctias and Thrascias and Argestes are associated with hail. Notus, Zephyrus, and Eurus are scorching. Caecias especially thickens the sky with clouds, Lips does so more intermittently; Caecias does so, because it bends back upon itself and because it is shared between the north and the east, so that because it is cold, it solidifies and composes the vaporizing air, while because it is eastern in its orientation, it has a lot of material and vapor which it pushes forward. Aparctias, Thrascias, and Argestes are associated with clear skies. The cause was stated previously.[79] These and Meses especially generate lightning. For because they blow from close at hand, they are cold; and lightning occurs because of the cold. For it is expelled when the clouds come together. That is why some of these same winds are associated with hail, because they solidify quickly.

78. Secluding καὶ εὖρος, ὃν ἀπηλιώτην ("and also Eurus, which some call 'Apeliotes'").
79. 364b7–10.

Cloud-wind-bursts occur mainly during the fall, then also during the spring; and **365ª1**
it is Aparctias, Thrascias, and Argestes that, most of all, occur then. The cause is that
the cloud-wind-bursts especially occur, when some winds blow and others confront
them, and these are the winds that most tend to confront the others when they are
blowing. The cause of this was also mentioned earlier.[80]

For those who live in the west, the Etesians veer around from Aparctias to Thrascias,
Argestes, and Zephyrus (for the Aparctias {. . .}[81] is a Zephyrus wind), starting from the
Bear and ending in those far off. But for those toward the east they veer toward Apeliotes.

So, let this be our discussion concerning the winds, their coming to be from a
starting-point, their substance, and their common and particular affections.

2.7
Previous Views on Earthquakes

Next, we must discuss the shaking and movement of the earth; for the cause of this
affection is the next one of its kind to be discussed. Up to the present time, at any
rate, three explanations have been handed down by three individuals: Anaxagoras of
Clazomenae and, earlier than him, Anaximenes of Miletus have made statements,
and latter than them Democritus of Abdera.

Anaxagoras claims[82] that the ether naturally travels upward, and when it hits the
lower parts of the earth and its hollows, it moves the earth; for the upper parts of
the earth are clogged because of the rain showers (since by its nature, at any rate,
the entire earth is uniformly porous). There is an upper part and a lower part of the
sphere as a whole, where the upper part is the one we happen to live upon, and the
lower part is the other.

Against this cause, perhaps one need not say anything in objection, since it is
stated in overly simple terms. For it is naive to think that the up and the down are
not so arranged that bodies having weight travel from every direction toward the
earth, while light bodies and fire travel up; especially since we see that the horizon
of the world, to the extent we know it, comes always to be different as we move—
implying that [the earth] is convex and spherical. And [it is also naive] to speak as
if it rests upon the air because of its size, and to claim that it is shaken when it is
struck from the bottom up through the whole of its extent. And in addition, he
gives no account of the affections that occur along with the earthquakes. For it is
not just any random region or season that are involved in these affections.

Democritus claims[83] that the earth is full of water and receives a lot of other **365ᵇ1**
rainwater, and that it is moved by this. For when the water becomes too much for the

80. $364^{b}3$–6.
81. There may be a lacuna in the text at this point.
82. A42.3, 12, A89 DK.
83. A97, 98 DK.

hollows to hold, it forces its way and produces an earthquake; and as the earth dries out, it draws water into empty places from those that are fuller, and the water as it is displaced, hits the earth, and thereby moves it.

Anaximenes[84] claims that the earth breaks up, as it is drenched and dries out, and that it is shaken when these broken mounds hit it. That is why earthquakes occur both during droughts and again in rainy periods. For during the droughts, as has been stated, the earth gets dried out and breaks up, and when it gets excessively wetted by rain, it falls apart.

But if this were the case, the earth should be visibly subsiding in many places. And again, what is the cause of this affection often occurring in some places that do not differ from others in point of this excess [of liquid]? And yet, they should. And, in general, those making this supposition must claim that earthquakes are always becoming weaker and that in the end the earth will stop being shaken; for what gets compacted has this sort of nature. So that if this is impossible, it is clear that it is also impossible for this to be the cause.

2.8
Aristotle's Theory of Earthquakes

Since it is clearly necessary that an exhalation is produced both from the wet and from the dry, as we said in our earlier remarks,[85] it is necessary that earthquakes occur when these things are present. For the earth is intrinsically dry, but because of rain showers, it contains a lot of liquid, so that when it is heated by the sun and the fire in the earth, wind occurs, a great deal outside and a great deal inside [the earth]. And this sometimes flows out all as a continuous whole, and sometimes it [flows] all inside, and sometimes it is divided up into portions.

So, if this cannot be otherwise, the next thing to consider would be what sort of body is the most susceptible to movement; for it is necessary for what is most naturally inclined to move and what is extremely violent to be most of all a thing of this sort. What moves fastest is necessarily what is most violent; for it hits hardest because of the speed. But what is most capable of moving through everything is the one that is most naturally inclined to pass through, and such a thing is the most fine-grained. So since the nature of wind is of this sort, wind is the most susceptible to movement of all the bodies. For whenever fire is present together with wind, it becomes flame and moves speedily. Therefore, neither water nor earth would be the cause of the movement, but rather wind is, when the exhalated wind that is outside [the earth] happens to flow inside.

That is why the largest and greatest number of earthquakes occur during periods of calm; for the exhalation, which is continuous, for the most part follows the

84. A7.8, 21 DK.
85. 341ᵇ6–10.

impulse of its starting-point, so that its impulse is entirely directed either toward the inside or toward the outside [of the earth]. But it is not unreasonable that some earthquakes occur even when wind is present; for we sometimes see several winds blowing at the same time, and whenever one of them has its impulse starting into the earth, there will be an earthquake, though there is wind. These ones become smaller in size, because their starting-point and cause is divided.

The larger and greater number of earthquakes occur at night, but those that occur during the day do so around noon. For noon is for the most part the calmest part of the day (for the sun, when it is most powerful, locks up the exhalation in the earth; and it is most powerful around noon); but nights are calmer than days because of the absence of the sun. Accordingly, the exhalation flows back in, like an ebb tide, in the direction opposite to the flood tide out, and this occurs mostly toward early dawn. For at that time, the winds naturally start to blow too. So if their starting-point happens to shift about, like the Euripus, toward the inside [of the earth], it produces a more violent earthquake because of the quantity.

Further, the most powerful earthquakes occur around the sorts of places where the sea is subject to flow or the ground is porous and cavernous, and that is why [they occur] around the Hellespont, Achaea, and Sicily and around these places in Euboea. For the sea seems to pass through channels under the ground, and that is why the hot springs around Aedepsus have also been produced. And earthquakes occur especially around the places that were mentioned because of the constriction of space; for the wind, the one that naturally vents forth from the earth, though it is violent, is pushed back into the earth[86] because of the great mass of the sea that is brought to bear upon it. And the regions whose lower places are porous receive a great deal of wind and are more subject to earthquakes. **366b1**

But they occur especially during spring and fall and in rainy and droughty conditions due to the same cause; for these seasons are most productive of wind. For the summer and the winter—the latter because of the frost, and the former because of the warmth—produce immobility; for the latter is too cold and the former is too dry. And in droughts the air is full of wind; for this is just what a drought is, when the dry exhalation becomes greater than the wet. But in excessively rainy periods, more exhalation is produced inside the earth. And when this sort of segregation is enclosed in narrower places and forced into a smaller place because the hollows are filled with water, and when the [wind] starts to prevail because a great amount of material is being compressed into a small space, the wind flows in forceful movement and strikes against the earth.

For we must think that, just as in our bodies, the enclosed capacity of the wind is the cause of shivers and pulsations, so also in the earth the wind does much the same thing, and that one mode of earthquake is like a shiver and another is like a pulse; and just as often happens after urination (for something like a shiver runs through the body as concentrated wind exchanges place from the outside in), so this also occurs

86. Secluding καὶ.

with the earth. And we must get a theoretical grasp on what capacity the wind has, not only from the things that occur in the air (for in this case one could well suppose that they are capable of doing such things because of their magnitude), but also from the things in the bodies of animals. For convulsions and spasms are movements of wind, and they have so much power that many people, though they try at the same time to apply force, are unable to overcome the movement of those afflicted. So—to liken bigger things to small—we must think that such a thing occurs in the earth too.

And signs of these things are also present to our perceptual modalities in many ways. For in some places, the earthquake does not cease, until the wind that moves it has clearly broken out into the place above the earth, like a cloud-wind-burst, and
367ᵃ1 departed, as for example came to be recently around Heracleia in Pontus, and earlier around the island of Hiera (this is one of the so-called Aeolian Islands). For there a part of the earth swelled up, and a hill-shaped mass rose up with a noise; and finally, when it ruptured, a great amount of wind issued forth and it emitted embers and ashes and entirely covered the nearby city of the Liparians with ash and reached some of the cities in Italy. Still today, it is clear where this blast occurred. In fact, we must think that this is the cause of the fire that occurs in the earth: when the air is first broken into small pieces, [the wind] is struck and ignited.

And what occurs around these islands provides a proof that winds flow under the earth; for whenever a wind is going to blow from the south, it first provides a sign in advance. For the places, from which the blasts are produced, resound because the sea has been pushed far away [by the blast], and then the blast from the earth is pushed back inside again by the sea at precisely the point where the sea meets it. And it produces a noise without an earthquake, because of the spaciousness of the places (for it overflows outside into the yawning gulf) and because of the small quantity of air that is pushed back.

Further, it is a sign of the cause mentioned that, in the absence of cloud, the sun becomes hazy and rather faint, and that sometimes there is a freezing calm before early dawn earthquakes. For the sun must be hazy and faint when the wind, which dissolves and disaggregates the air, starts to subside into the earth; and at dawn and first light there must be calm and cold. For calm must result for the most part, as was said previously,[87] since the flow of the wind has shifted toward the inside of the earth, and more so before bigger earthquakes: for if [the wind] inside and [the wind] outside are not pulled apart from one another, but move spatially together in a concentrated mass, a greater force must result. And the cold occurs because the exhalation, which by nature and intrinsically is hot, turns inside [into the earth].

Winds do not appear to be hot, because they set the air in movement, which is full of a great deal of cold vapor, just like breath[88] when it is blown through the mouth.
367ᵇ1 For it is hot from near at hand, just as when we breathe with the mouth wide open, but it is not as obvious because of the small quantity, while from far away it is cold

87. 366ᵃ5–8.
88. Rejecting the addition of τὸ.

due to the same cause as the winds. So when this sort of capacity [the dry exhalation] departs into the earth, the vaporous flow, coming together because of the liquid, produces cold, in the places in which this affection happens to occur.

The same cause is also the cause of a sign that tends to occur sometimes before earthquakes. For either in broad daylight or a little after sunset, when the sky is clear, a long, delicate, little cloud appears stretched out, like a long, very straight line, since the wind has faded away because of its removal [into the earth]. A similar thing also happens at sea near the shore. For whenever the swell of the sea casts [waves] ashore, the waves become very massive and crooked; but whenever there is a stillness, because the segregation is small, the waves are delicate and straight. So what the sea does in the vicinity of the land, the wind does with the mist in the air, so that whenever there is calm, a cloud is left behind, altogether straight and delicate, as if it were a wave of air.

Due to these things too an earthquake sometimes happens to occur around the time of the eclipse of the moon. For when the occlusion is already near, but while the light and the heat from the sun have not yet altogether gone from the air, but have already faded away, a calm occurs, as the wind shifts its place into the earth, and this produces the earthquake prior to the eclipses. For winds often also occur before eclipses: at nightfall before eclipses that occur at midnight; and at midnight before dawn eclipses. This occurs because the heat from the moon has faded at a time, when its spatial movement is already close to the place where, under the circumstances, the eclipse will occur. But when that by which the air is restrained and at rest, is relaxed, the air moves again, and wind occurs, and it does so later when the eclipse is later.

When a powerful earthquake occurs, it does not stop shaking immediately or all at once, but at first it continues often up to around forty days, and later earthquakes are in evidence for one or two years in the same places. And the amount of wind and **368^{a}1** the configuration of the places through which it flows are the cause of the magnitude [of the earthquake]. For wherever it meets some obstruction and does not easily pass through, it causes the greatest shaking and necessarily gets trapped behind in confined places, like water in a vessel that cannot escape. That is why, just as in [an animal's] body, the pulses do not cease suddenly or quickly, but only gradually, as the affection fades, so the starting-point from which the exhalation arose and the impulse of the wind clearly did not immediately consume the entirety of the material, from which it produced the wind we call an "earthquake." So until the rest of it is consumed, there is bound to be shaking, albeit more gentle, until the exhaled material becomes too slight to be able to impart any obvious movement.

The wind also produces the noises that occur under the earth including the ones before the earthquakes; and even without earthquakes noises have been observed to occur in certain places under the earth; for just as the air emits all manner of noises when it is being beaten, so it does when it itself is doing the beating; for it makes no difference; for in every case what strikes is itself also struck at the same time. And the noise precedes the movement, because the noise is made of more delicate parts and is better able to make its way right through than the wind. And whenever the

wind, because of its delicacy, is too slight to move the earth, it is incapable of moving it because it easily penetrates; but because it meets with masses, solid and hollow and of all manner of shapes, it emits all manner of sounds, and as a result the earth sometimes seems to bellow, as the tellers of monstrous tales say.

We have also seen water break out when earthquakes occur, but this does not mean that the water is the cause of the movement [of the earthquake]; rather the wind does the moving, whether it is on the surface or forces its way from below (just as the winds are the cause of the waves and not the waves the cause of the winds), since someone might assign the earth as a cause of the affection as well; for the earth, when it is shaken, is overturned, just as water is (for the pouring out of water is a form of overturning). But both these things are causes as matter (for they undergo affections but are not active), while the wind is cause as a starting-point.

Where a wave occurs at the same time as an earthquake, the cause arises whenever the winds are opposed to one another; and this occurs whenever the wind that shakes
368b1 the earth is unable fully to push the sea away, because it is being moved by another wind; but by pushing the sea forward and drawing it back, it gathers together a great amount of sea into the same space. For when this wind has been overcome, the sea is necessarily pushed into a concentrated mass by the opposite wind, then breaks out and produces the tsunami. This happened around Achaea too.[89] For the south wind was outside, and the north wind was there, and during a calm, as the wind was flowing inside, a wave and an earthquake came to be at the same time, and more so because the sea did not give vent to the wind whose impulse was initiated under the earth, but rather blocked it. For as they forced one another, the wind produced the earthquake, and the subsidence of the wave produced the tsunami.

Earthquakes occur here and there on the earth, and often in a small place; but the winds do not. They occur here and there, whenever the exhalations in the place itself and the neighboring place join together into one, just as we claimed[90] that localized droughts and heavy rains occur. And the earthquakes occur in this manner too, but the winds do not; for some things have their starting-point in the earth, so that all the exhalations have an impulse toward one place; but the sun cannot similarly make the upper exhalations—whenever they get their starting-point of movement from the spatial movement of the sun—to flow into one area according to the particular differences of the places.[91]

Whenever there is a lot of wind, it moves the earth like a shiver, side to side. But occasionally and in some [specific] places, it occurs up and down, like a pulse. That is why only rarely does the earth shake in this manner; for it is not easy for a lot of starting-points to collect in this way; for the disaggregation occurs along the length many more times than along the depth. And wherever such an earthquake occurs, a mass of

89. In 373–2 BC.

90. 360b17–26.

91. Reading ὁ δ' ἥλιος οὐχ ὁμοίως δύναται τὰς μετεώρους—ὅταν ἀρχὴν λάβωσιν ἀπὸ τῆς τοῦ ἡλίου φορᾶς—ὥστε ῥεῖν ἤδη κατὰ τὰς διαφορὰς τῶν τόπων ἐφ' ἕν.

stones comes to the surface, just as with things being thrown up in winnowing fans. For when an earthquake came to be in this way, the [land] around Sipylus and the so-called Phlegraean plains and the area around Liguria were overturned.

Earthquakes occur less on the islands of the sea than on those close in to land; for the mass of the sea cools the exhalations and blocks them by its weight and brings force upon them. And again, it flows and is not shaken, when mastered by the winds. And because it extends over a great space, the exhalations occur not into it but out of it, and the exhalations from the earth follow them. But the islands near the mainland are a part of the mainland; for what is in between, due to its smallness, has no capacity. And it is not possible to move the islands out at sea without moving the whole sea, by which they happen to be surrounded.

We have now discussed pretty much the most important issues concerning earthquakes, what their nature is, due to what cause they occur, and the other circumstances surrounding them.

2.9
Thunder and Lightning

Let us discuss lightning and thunder, and again tornados, fire-tornados, and lightning bolts; for we must suppose that there is the same starting-point for all of these.

For since the exhalations are twofold, as we have said,[92] the wet and the dry; and since the aggregation has both of these potentially and is composed into a cloud, as was said previously;[93] and further, since the composition of the clouds becomes thicker toward the extreme border (for where the hot part disaggregates and departs toward the upper area, the composition must be thicker and colder there, which is why the lightning bolts and the cloud-wind-bursts and all such like travel downward, and yet everything that is hot naturally travels upward; but it is necessary for the squeezing out to occur in the direction opposite to the thickness, like pips popping out from between the fingers; for these things, though they are heavy, often travel upward)—the excreted heat is scattered across the upper place, and however much dry exhalation is enclosed during the change as the air cools, is excreted as the clouds come together, and as it is spatially moved by force and falls upon the surrounding clouds, it produces an impact, whose noise is called "thunder." The impact occurs in the same way, to compare a little affection with a bigger, as the noise that occurs in a flame, the noise some call "Hephaestus' laugh," others call "Hestia's laugh," while others call it their "threat." It occurs whenever an exhalation is contracted and carried toward the flame, when the wood is broken and dried. For in clouds likewise, the wind gets excreted, strikes against the dense clouds, and produces thunder. And

92. E.g., $341^{b}6$–10.
93. $341^{b}36$–$342^{a}3$, $346^{b}23$–31, $358^{a}21$–6, $359^{b}29$–34.

369ᵇ1 all manner of noises occur due to the irregularity of the clouds and the hollows in between, where their density lacks continuity.

This, then, is what thunder is, and it occurs due to this cause. And the wind that is squeezed out, burns for the most part with a delicate and weak flame, and this is what we call "lightning," wherever wind, driven out, as it were, is seen to take on color. It occurs after the impact and later than the thunder, but it appears to occur before, due to sight coming before hearing. This is clear in the case of the rowing of triremes; for as the crew is already bringing back their oars, the first noise of the striking of the oars arrives.

And yet some people say that the fire occurs *in* the clouds. And Empedocles claims[94] that this fire is the rays of the sun that are enclosed [in the cloud]. Anaxagoras says[95] that it is the part of the upper ether [that is enclosed] (which he calls "fire"), and which has been brought down below from above. [They say that] the radiance of this fire is lightning, and the noise of the extinguished fire and the hissing is thunder, on the grounds that it occurs just as it appears, and that the lightning is before the thunder.

But the enclosing of the fire makes no sense in either way, but especially the drawing down of the ether from above. For a cause must be stated for what naturally moves spatially upward moving downward, and why it is that this occurs in the sky only when it is cloudy, and not continuously so. It does not occur when [the sky] is clear. Indeed, this [explanation] seems to have been stated altogether offhandedly. Similarly, it is not persuasive to claim that the heat from the rays that is intercepted in the clouds is the cause of these things. For this account is stated without sufficient care; for it is necessary that the cause be something separate and determined in each case, a cause for thunder, a cause for lightning and so on, and they should occur accordingly. But this account is completely different; for it is as if someone were to think that rain and snow and hail were previously present and later excreted, and did not come to be, since the aggregation always produced each of them as if they were at hand. Likewise, one must suppose that rain, snow, and hail are aggregations and that thunder and lightning are disaggregations, so that if one of the two does not come to be but exists [beforehand], the same account will fit both cases. And as for the interception, why would one claim anything different from what happens in the case of denser media? For water also comes to be hot by the sun and fire. Nonetheless, when the vapor comes back together and the water is cooled and solidified, no ejection occurs such as they claim. And yet it should, at least according to the proportion of the magnitude [of the vapor]. And the wind that comes to be in [the cloud] because of the fire produces a boiling, which cannot be residing previously; nor do they make the noise a boiling but a hiss. But a hiss too is a small boiling; for wherever what makes contact prevails by being extinguished, it produces the noise by boiling.

And there are some, like Cleidemus, who claim that lightning does not exist, but is an appearance, comparing the affection to like what happens when one strikes the

94. A63 DK.
95. A1.9, A42.11, A84 DK.

sea with a rod; for, during the night, the water clearly sparkles. So, he claims, when the liquid in the cloud is struck, the lightning is the appearance of the brightness. These people were not yet acquainted with the [current] beliefs about reflection, which seems to be exactly the cause of this sort of affection; for the water appears to sparkle when struck, because the ray of sight is reflected from it toward some shining body. That is why this occurs more at night; for during the day, it does not appear, because the greater light of the day makes it invisible.

These are the things, then, that are said about thunder and lightning by others, some saying that lightning is a reflection, others that lightning is the radiance of fire and thunder is its extinction, while the fire does not come to be in each of these affections but is present [in advance]. But we claim that the same nature is a wind upon the earth, earthquake in the earth, and thunder in the clouds. For all these are the same in substance—a dry exhalation, which when it flows in a certain way is a wind, in another way it produces earthquakes, and as it shifts and disaggregates in the clouds and the clouds come together and aggregate into water, it is thunder and lightning and the other things too, which are of the same nature as these. We have now discussed thunder and lightning.

BOOK 3

$370^{b}1$

3.1
Tornadoes and Fire-Tornados

Let us continue in the way that we have already established, and speak about the remaining effects of this segregation.

For this wind, when it is segregated out little by little and is dispersed here and there, occurs in frequent gusts, and is composed of finer-grained parts, produces thunder and lightning. But if it is concentrated and denser, and is segregated out with less fine-grained parts, a cloud-wind-burst occurs. That is why it is violent (for the speed of the segregation produces the strength).

Whenever a lot of continuous segregation accompanies it, the phenomenon occurs in the same way as when its impulse starts back to the [tendency of the] opposite [exhalation];[96] for then rain and a mass of water is produced. Both of these are potentially present in accord with their matter, and, whenever the starting-point of one of the two capacities is produced and aggregates, the aggregation of whichever material is present in the greater amount follows, and becomes either rain or, in the case of the other exhalation, a cloud-wind-burst.

And whenever the wind segregated out in the cloud strikes against another, as when a wind forces its way from an open area into a narrow space, in gateways or streets (for it

96. Cf. $360^{b}15–26$.

often occurs in such places, when the first part of the flowing body is pushed out of the way—because of a body that does not yield, either because of its narrowness or because of counter-winds—that a circle and whirlwind occur; for what is in front prevents it from moving forward, while what is behind pushes it on; so it is forced to move spatially sideways, where it is not blocked, and each part in turn does likewise, until it becomes a unity, and this is a circle; for the shape for which there is one spatial movement must itself be a unity). Due to these things, then, whirlwinds occur on the earth; and likewise in the clouds at their starting-point, except that just as, when a cloud-wind-burst occurs, it is continually segregated out from the cloud[97] and a continuous wind occurs, so here a continuous cloud always follows. But due to its density, the wind cannot be segregated out from the cloud, and turns in a circle at first for the stated cause, and is carried downward because of the continuing condensation of the clouds where the hot material is ejected.

And this affection is called a "tornado," if it is uncolored, being a wind that is like an unconcocted cloud-wind-burst. Tornados do not occur along with north winds, nor does a cloud-wind-burst occur when the winds are snowy,[98] because all these things are wind, and wind is a dry and hot exhalation. So the frost and cold, because of their mastery, immediately extinguish the starting-point [of wind] as it is still coming to be. And it is clear that they are mastering; for otherwise there would be no snow, nor would the liquid be from the north; for these things occur when the cold is mastering. A tornado occurs when the cloud-wind-burst that is in the process of coming to be is unable to get segregated out from the cloud. And it remains in existence because the whirlwind is obstructed, as the spiral travels toward the earth, dragging the cloud along with it, and is not able to escape it. But where it blows forth along a straight path, here it imparts movement because of its wind, and with its circular movement it turns and carries up whatever it encounters in its violence.

Whenever it is drawn down and bursts into flames (this happens if the wind becomes more finely grained), it is called a "fire-tornado." It also causes the air to ignite and take on color because of the fire.

And if within the cloud itself a great deal of fine-grained wind is squeezed out, this becomes a lightning bolt: if it is very fine-grained, and does not scorch because of its fine-grainedness, it is what the poets call "bright white," but if it is less fine-grained, and scorches, it is what they call "sooty."[99] For the former travels because of its fine-grainedness, but due to its speed it passes through before it burns it thoroughly or blackens it by lingering on it. But the slower one causes coloration, but does not burn, and instead first [passes through]. That is why some things, upon resisting, suffer some affection, while others do not resist and suffer nothing, as in the case of the shield—the bronze trimming was melted, while the wooden part suffered no affection. Because of the rare quality [of the material], the wind first filtered through and passed out. And in the same way, it does not burn through clothes, but makes them like a tattered rag.

97. Reading τοῦ νέφους.
98. Reading νιφετῶν ὄντων.
99. Homer, *Iliad* 8.133, *Odyssey* 23.330, 24.539.

So it is clear from such considerations, at any rate, that all these things are wind, and sometimes we can see it with our own eyes too, as with the sort of thing we saw in the burning of the temple at Ephesus;[100] for the flame was drawn apart and carried continuously in many directions. For it is evident that both smoke is wind and smoke burns, as we have stated elsewhere previously;[101] and whenever [fire] moves in a concentrated way, then it is clearly seen to be wind. So what is apparent in the case of small conflagrations, the very same thing came to be in that case too, and much more strongly, because a great deal of wood was burning. So when the wood cracked, which was the starting-point and source of the wind, a great deal of it made its way in a concentrated fashion where it blew outward and was carried upward aflame. As a result, the flame appeared to travel and to fall upon the houses. For we must think that in every case wind both follows the lightning bolts and goes in advance, but it is not seen because it is uncolored. That is why the object, which [the lightning] is going to strike, moves before being struck [by the lightning itself], since the starting-point of the wind strikes it first. And thunder splits things not by its noise, but because the wind that produces the strike and the one that produces the noise are segregated out at the same time. And if it strikes, it causes the split but does not burn.

We have now spoken about thunder and lightning and cloud-wind-burst, and again about fire-tornados and tornados and lightning bolts, [showing that] they are all [different sorts of] the same thing, and how all of them differ.

3.2
Phenomena of Reflection

Let us discuss the halo and the rainbow, what each of them is, and due to what cause each of them occurs, and also parhelia[102] and rods; for all these things occur due to the same causes as each other. But it is necessary first to grasp the affections and the circumstances associated with each of them.

A halo often appears as an entire circle. It occurs around the sun and moon and the other bright heavenly bodies (*astrôn*), and again no less during the night than during the day, around midday or afternoon, but less often at dawn and sunset.

A rainbow never occurs as a circle, nor any section greater than a semicircle. At sunset and sunrise the circle is the smallest while the arc is the greatest; and when the sun is higher and the circle greater, the arc is smaller. After the fall equinox, during the shortening days, it occurs during every hour of the day, but during the summer days, it does not occur around midday. Nor, in fact, do more than two rainbows occur at the same time. And each of them has three colors, and the colors are the same and equal in number to one another, but the colors on the outside rainbow are dimmer and are

100. 356 BC.
101. 341ᵇ21.
102. Also known as sun dogs or mock suns.

reversed in their placement. For the inside rainbow has its first circumference, the biggest one, crimson, while the outer one has its smallest circumference, the one nearest to the [inside rainbow], crimson, and the other circumferences are in corresponding order. These colors are pretty much the only ones that painters cannot produce. For they themselves mix some colors, but crimson, green, and purple are not produced by mixing. But the rainbow has these colors. What is between crimson and green often appears yellow.

Parhelia and rods always occur on the sides [of the sun] and neither above it nor near the earth, nor opposite [the sun], nor in fact at night, but always around the sun, and again either when it is rising or descending, and mostly around sunset. At zenith it occurs only rarely, if at all, as once happened in the Bosporus. For through the whole day two parhelia rose together [with the sun] and persisted right up to sunset.

These are the circumstances surrounding each of them. The cause of them all is the same; for all these things are reflections. But they differ in their manner and their source, and how the reflection happens to occur toward the sun or some other bright body.

A rainbow occurs during the day; but according to what the ancients used to think, no rainbow occurs from the moon at night. This thought was imposed on them because of the rarity of the occurrence; for it escaped their notice; for it does occur, though seldom. The cause is that we fail to notice colors in the darkness, and it is necessary for many other circumstances to coincide, and for all of these to occur on one single day in the month; for it must occur at the full moon, if it is going to happen, and then when the moon is rising or setting. That is why we have only encountered it twice in over fifty years.

That the ray of sight is reflected, just as it is from water, also from the air and from everything that has a smooth surface, we must be persuaded of from the facts proved about sight, and also that in some mirrors the shapes [of the objects] appear, but in others only the colors. Small mirrors, and those that have no perceptible division, are
372b1 of this sort; for the shape cannot appear in these (for otherwise, it will appear to be divisible; for every shape seems at the same time to be a shape and to be divisible); and since it is necessary for something to appear, but shape cannot, it remains that only the color appears. The color of bright objects sometimes appears bright, but sometimes, either because of the mixture [with the color] of the mirror or the weakness of our sight, it produces the appearance of a different color.

Let this be what has been grasped theoretically by us about these things in our proofs concerning perception. That is why we may explain some things but make use of others as givens.

3.3
The Halo

First, let us speak about the shape of the halo, why it becomes a circle, and why [it appears] around the sun or the moon and similarly around any of the other heavenly bodies; for the same account will fit all cases.

A reflection of the ray of sight occurs when air and vapor are being composed into cloud, if the composition happens to be even and made of small parts. That is why this composition is a sign of rain; but [when it is being] pulled apart or caused to fade away, the fading away is a sign of good weather and the pulling apart a sign of wind. For if it is neither caused to fade away nor pulled apart, but is allowed to attain its nature, it is likely a sign of rain; for it is clear that at this point the composition becomes of such a sort that it achieves the continuous density necessary to become rain. That is why these compositions become of a blacker shade than the others. But whenever they are pulled apart, it is a sign of wind; for the dispersal occurs due to a wind that already exists but is not yet present. And there is sign of this in that the wind occurs from where the pulling apart takes control. And when it is caused to fade away, it is a sign of good weather; for if the air is not in a state to master the enclosed heat nor to proceed to rainy density, it is clear that the vapor has not yet separated from the dry and fiery exhalation. And this is the cause of good weather.

We have now described the condition of the air under which a reflection occurs. The ray of sight is reflected from the mist that is being composed around the sun or the moon. That is why the halo does not appear opposite [the sun], as the rainbow does. And since the ray of sight is reflected equally from all directions, the halo must be a circle or a part of a circle. For equal lines will always be bent from the same point to the same point upon the line of a circle [Fig 4].

373^{a}1

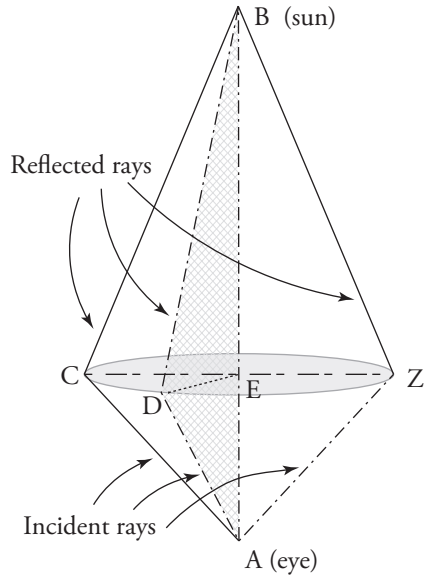

Fig. 4

For let the lines ACB, AZB, and ADB be bent from the point A to the point B. And let lines AC, AZ, and AD be equal to one another, and the lines to B equal to one another, that is, lines CB, ZB, and DB. And let line AEB be joined, so that the triangles

are equal; for they are on the equal line AEB. And let perpendiculars be drawn to AEB from the angles: from C the line CE, from Z the line ZE, and from D the line DE. These, then, are equal; for they are all in equal triangles and in a single plane; for they are all at right angles to AEB and touch at one point, E. Therefore, the line drawn will be a circle, and the center will be E. B is the sun, A the [organ of] sight, and the circumference around CZD is the cloud from which the ray of sight is reflected to the sun.

It is necessary to suppose that the mirrors are continuous. But because of their smallness, each is invisible; but the composite of all of them seems to be a unity because of their continuity. It appears as white, that is, the sun, appearing continuously in each of the mirrors in a circle, as long as it has no visible divisions, and rather near the earth, because it is relatively calm; for where there is wind, there is clearly no stillness. The circumference next to this is comparatively dark, taking on a darker appearance because of [the other's] whiteness.

Halos often occur around the moon because the sun, which is hotter, more quickly dissolves the compositions of the air. And they occur around the stars due to the same causes, but are not signs [of weather] in the same way, because the compositions they make apparent are altogether small and not yet productive [of rain].

3.4
Rainbows

It was said previously that the rainbow is a reflection. But let us now discuss what sort of reflection it is and how and due to what cause each of the circumstances surrounding it occurs.

A ray of sight is clearly reflected from all smooth surfaces, and among them are both
373[b]1 air and water. Reflection occurs from air whenever it happens to be getting composed. But air often produces a reflection even without a composition because of the weakness of the ray of sight. This affection, for example, once happened to someone whose sight was weak and not sharp; for an image appeared to move in front of him continually as he was walking, looking at him face to face. He was affected in this way because the ray of sight was being reflected to him; for the ray of sight was so altogether weak and delicate because of his affliction, that even the nearby air came to be a mirror—as the far off and dense [air is a mirror]—and [the ray of sight] was not able to push it off. That is why headlands appear as drawn up in the sea, and the magnitudes of all things appear bigger whenever the Eurus winds blow, and also things in the mist, for example, the sun and the stars, [appear bigger] as they rise and set than when they are at midday.

There is reflection especially from water, and more still from what is starting to become water than from air; for each of the parts, from which droplets are produced when their parts get composed, must be a mirror more than mist is. And since it is clear and was said previously[103] that in such mirrors the color alone appears, while the

103. 372[a]29–[b]11.

shape is unclear, it is necessary—whenever it begins to rain and the air in the clouds is already getting composed into droplets, but it is not yet raining, if the sun or some other body is opposite and so bright that the cloud becomes a mirror and a reflection occurs toward the bright body opposite—that an appearance of color, and not of shape, occurs.

Although each of the mirrors is small and invisible, because the continuity of the magnitude of all of them is visible, it is necessary that a magnitude of the same color appears continuous; for each of the mirrors produces the same color as the continuous [whole], so that, since these things can occur, whenever the sun and the cloud are in this state and we are in between them, there will be some image because of the reflection. In fact, it is evident that the rainbow occurs at that time, and not when circumstances are different.

So it is evident that the rainbow is a reflection of the ray of sight to the sun. That is why it always occurs opposite [the sun], while the halo occurs around the sun. And yet both are reflections. But the variety of their colors is different; for the former reflection is produced from rain and black [surfaces] and also from a distance, while the latter from closer and from air, which is whiter by nature. The bright object appears crimson through the black or in the black (for it makes no difference); and it is possible to see how the fire of green wood has a red flame because the fire, though it is bright and white, is mixed with a lot of smoke. Through mist and smoke, the sun appears crimson as well. That is why the first reflection [that is, the first band] of the rainbow appears to have such a color (for the reflection is produced from small drops), while that from the halo does not. (Concerning the other colors we will speak later.[104]) And again, such a composition does not linger long around the sun itself, but it either rains or dissolves. But [in the reflections] on the opposite side, some time passes while the rain is coming to be; for if this did not happen, the halos would be colored, just like the rainbow. As it is, however, nothing occurs with this sort of appearance, neither as a whole, nor in a circle but small and only partly (they are called "rods"), since if a mist were being composed of the sort that would be produced from rain or some other black surface, as we say, the rainbow would appear in its entirety, just like around a lamp flame.

For a rainbow occurs around lamps for the most part when there is a south wind during the winter, and it is especially clear for those who have wet eyes; for the ray of sight of these people is reflected quickly because of its weakness. And the rainbow is produced from the liquid in the air and from the soot that flows from the flame and is mixed with it; for it is at that time and due to the blackness, that the mirror is produced; for the soot is smoky. The light of the lamp is not white, but appears as purple, in a circle and rainbow-like, and not crimson; for the reflected ray of sight is slight, and the mirror is black. And as far as their position is concerned, the rainbow associated with oars being drawn back out of the sea occurs in the same way as rainbows in the sky, though their color is more like that around lamps; for it makes its appearance

104. $374^{b}7$–$375^{b}15$.

with a purple rather than crimson color. And the reflection occurs from very small but continuous drops. And these are rain that has been already utterly separated.

[A rainbow] also occurs if one sprinkles delicate drops into a place whose position is turned toward the sun and which is occupied by the sun in one place, but in another is in shadow; for in this sort of place, if someone sprinkles water inside, a rainbow appears to one who stands outside, where the rays cross over and produce shadow. The manner [of the rainbow] and its color are similar to that associated with oars, and their cause is the same; for the sprinkler uses his hand as an oar.

That it is this sort of color will be clear at the same time concerning the appearance of the other colors as well from the following considerations. For it is necessary for us to understand and lay down, as was said,[105] first, that in a black medium or through a black medium something bright produces a crimson color; second, that the ray of sight as it is extended becomes weaker and slighter; and, third, that the black is a sort of negation; for it appears black because of the failure of the ray of sight. That is why all things appear blacker from a distance, because the ray of sight does not reach them.

Let us get a theoretical grasp on these things in light of the circumstances concerning perception. For the accounts of these things are special to those. But for now, let us say as much about them as is necessary. It is due to this cause that things far away as well as the things in mirrors appear blacker and slighter and smoother, and clouds appear blacker to those looking into water than into the clouds themselves. This is altogether obvious; for because of the reflection they see with a reduced sight. And it makes no difference whether the object of sight changes or the ray of sight does; for either way it will be the same. In addition, we must not lose sight of this either: for it happens that, whenever a cloud is near the sun, nothing appears colored to the person who is looking at it, but rather it appears to be white; for one viewing this very thing in the water, however, it has some rainbow coloring. It is clear, then, that just as the ray of sight, when it is bent because of weakness, makes the black object appear blacker, it also makes the white less white and brings it closer to the black.

The stronger ray of sight changes it to the crimson color, while the next changes it to green and the one still weaker to purple. No further color than this appears, but they come to completion in these three, just as with most other things; for the change to the other colors is imperceptible. That is why the rainbow appears tricolor, both the one and the other, though in an opposite order. The first, then, has the crimson outside; for from the largest circumference the greatest ray of sight falls toward the sun, and the outside is the biggest. The next and the third circumference are proportional, so that if we have described the facts concerning the colors of the appearance well, it is necessary that it be tricolor and make use of these colors alone. The yellow appears because of the two colors appearing next to each other; for the crimson appears white next to the green. A sign of this is that the rainbow becomes most unmixed in the blackest cloud, and in such conditions the crimson appears more yellow. The yellow color in the rainbow is in between

105. 374ª3–8.

the crimson and the green color. So, due to the darkness of the cloud round about, the whole of the crimson part appears white; for it is white in relation to them. And again, it occurs when the rainbow is close to being completely faded away, when the crimson is being dissolved; for the cloud, which is white, falls up against the green, and changes over to yellow. The rainbow from the moon is the best sign of these things; for it appears altogether white. And this occurs because it appears in the dusky cloud and during the night. So just like "fire upon fire," black next to black makes what is slightly whiter appear altogether white. And this is the crimson. And this affection becomes obvious in the case of embroidered flowers on garments too; for in weavings and embroideries there is an indescribable difference in appearance when one color is placed next to another, for example, purple against white or black wool, and again in this or that light. That is why embroiderers say that they often make errors about the colors when they work by the light of the lamp and pick up one color rather than the other.

We have described why the rainbow is tricolor, then, and why it appears to consist in these colors alone. The rainbow that surrounds the first is a twin but dimmer in color, and it displays the opposite placement of colors due to the same cause; for the ray of sight, because it is stretched out to a greater length, views the object in this case in the same way as it does the remoter object. So the reflection from the outside rainbow becomes weaker, because the reflection produced is further off, so that, when it strikes **$375^{b}1$** in its diminished state, it makes the colors appear dimmer. And in reverse order, because more of the ray of sight falls upon the sun from the smaller circumference, the inside one; for since it is nearer to the ray of sight, it is reflected from the circumference closest to the first rainbow. And the smallest circumference is the nearest in the outside rainbow, so that it itself will have the crimson color. And the next and the third will be proportional.

The outside rainbow is at B [Fig. 5]; the inner one, the first, is at A; and the colors, at C the crimson, at D the green, and at E the purple. The yellow appears at Z. But three or more rainbows do not occur, because even the second becomes dimmer, so that the third reflection becomes altogether weak and is unable to reach the sun.

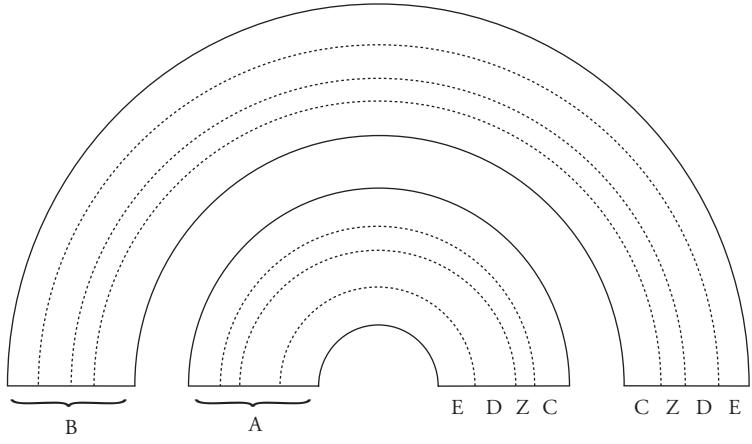

Fig. 5

3.5
The Geometry of Rainbows

Among the other circumstances surrounding the rainbow, it will be clear to those who consider the diagram, that it can occur neither as a circle nor any section larger than a semicircle.

For if there is a hemisphere on the horizon circle at A, and a center K, and some other point rising at H, and if the lines from K fall in the manner of a cone and produce, as it were, an axis [of the cone] on line HK, and the lines from K joined to M are reflected from the hemisphere to H over the greater angle, then the lines from K will fall upon the circumference of a circle [Fig. 6].

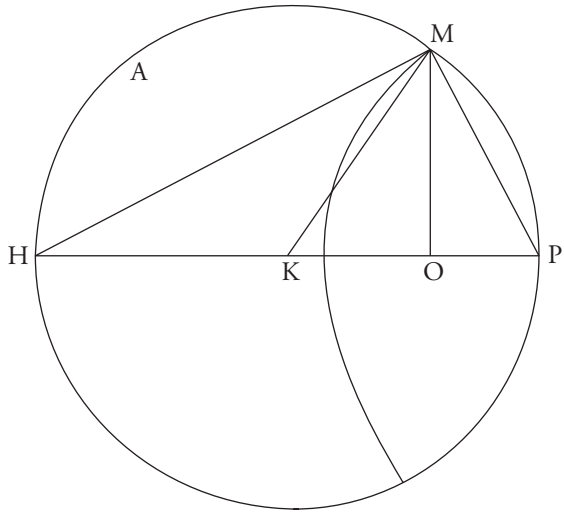

Fig. 6

And if the reflection occurs upon the rising or setting of the heavenly body, the part of the circle that occurs above the earth will be cut off by the horizon as a semicircle, but [if the reflection takes place] above that, it will be in every case less than a semicircle. And it will be smallest, whenever the heavenly body comes to be on the meridian.

First, let it be at the rising at H, and let the line KM be reflected to H, and let the plane on line A, the one from the triangle in which HKM is, be produced [Fig. 7]. Therefore, the section of the sphere will be a great circle. Let this be the circle at A; for it will make no difference which plane on HK is produced in accord with the triangle KMH.

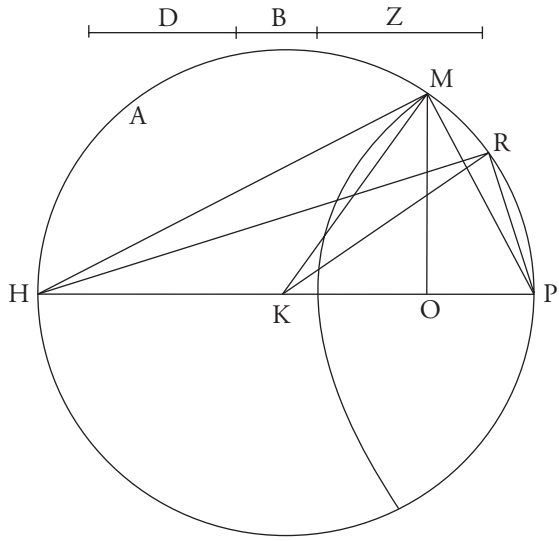

Fig. 7

{Therefore, the lines drawn from H and K will not meet together in this proportion at **376a1**
any arbitrary point of the semicircle A; for since the points K and H and the line HK are
given, the line MH would also be given, so that the proportion of the line MH to MK
also [would be given]. Since, then, the circumference is given, M will touch it. Let this
be [the line] upon which points N and M are located, with the result that the section of
the circumferences is given. [Lines having] the same proportion and being in the same
plane do not meet together from the same points at any other circumference than MN.

Let some line DB be set out, then, and let D be cut in proportion to B as MH is
to MK. MH is greater than KM, since the reflection is toward the greater angle of the
cone, since it subtends the greater angle of the triangle KMH. Therefore, the line D is
greater than the line B. So, let there be added to the line B the line Z, so that what D
is to B, BZ is to D. Then what the line Z is to KH, let the line B be made to another
line, line KP, and let the line MP be joined from P to M.

P will then be the pole of the circle on which the lines from K meet; for what the
line Z is to KH, the line B will be to KP, and the line D will be to PM. For let it not
be so, but rather [to a line] less or greater than PM (for it will make no difference). Let
it be in proportion to PR. Therefore, the lines HK and KP and the line PR will have
the same proportion to one another as the lines D, B, and Z. But the lines D, B, and
Z were in proportion: as the line D was to B, the line ZB was to D. So what PH is
to PR, the line PR is to PK. If, then, the lines HR and KR are joined from K and H
to R, these joined lines will have the same proportion that HP has to PR; for around
the same angle P the lines of the triangles HPR and KRP are proportional, so that the
line HR[106] will also have the same proportion to KR as the line HP to PR. And the

106. Reading HR.

line MH will have this proportion to KM; for they both have the same proportion as
376[b]1 D to B, so that not only do they meet the circumference MN in the same proportion from the points H and K, but also from elsewhere. But this is impossible. So, since the line D is proportional neither to a line smaller than MP nor to one bigger (for it will be proved in a similar manner), it is clear that it would be proportional to that at MP itself, so that what MP will be to PK, PH is to MP, and finally the line MH to MK.[107]

So, if a circle is drawn using the point P as a pole and the line MP as a distance, it will touch all the angles, which the lines from the circle MA make upon reflection. Otherwise, the lines meeting arbitrarily on the semicircle will similarly be shown to have the same proportion, which is precisely what was impossible.}[108]

If, then, one circumscribes the semicircle on A around the diameter HKP, the lines reflected from HK will be similarly related to M in all the planes, and will make the angle KMH equal. And the angle that the lines HP and MP make on HP will be equal in every case. So the triangles on HP and KP are equal to the triangles HMP and KMP. And their perpendiculars will fall upon the same point of HP and will be equal. Let them fall upon O. Therefore, O will be the center of the circle, and the semicircle around MN will be intercepted by the horizon.

{For [they claim] the sun does not master the upper area but masters the things that are aloft nearby and scatters the air. And that is why the rainbow does not create a circle. And it occurs at night as well from the moon, though rarely; for the moon is not always full and it is too weak in its nature to master the air, but the rainbow arises especially where the sun is especially mastered; for the greatest amount of mist remains in the rainbow.}[109]

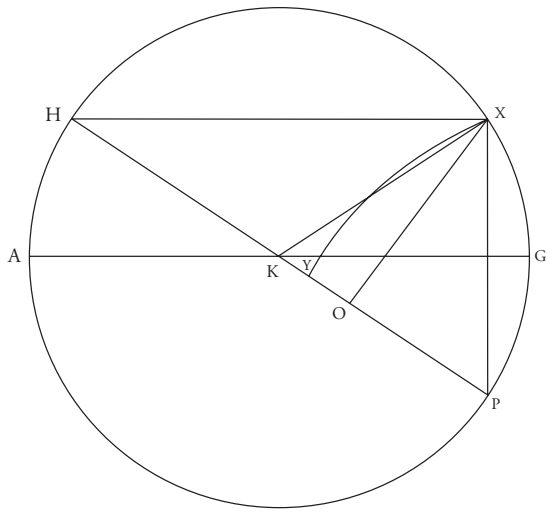

Fig. 8

107. Reading καὶ λοιπὴ ἡ τὸ ΜΗ πρὸς ΜΚ.
108. The bracketed passage (376[a]1–[b]12) is almost certainly an interpolation.
109. This paragraph is out of place and corrupt.

Again, let the horizon be at AKG, and let H already have risen, and let the axis be now at HP [Fig. 8]. Then all the other things will be proved as previously, but the pole of the circle at P will be below the horizon AG, since the point H is raised. The pole, the center of the [rainbow] circle, and the center of the circle now defining the rising point (for this is the circle HP) are on the same line. And since KH is above the diameter AG, the center [of the rainbow] would be below the horizon previously on the line AG, on the line KP at O.[110] So the section above, that at XY, will be smaller than a semicircle; for XYO was the semicircle, but now it is cut off by the horizon AG. The part OY of it, then, will be invisible, when the sun has risen up, and [the visible rainbow] will be smallest when [the sun] is at midday; for the higher H is, the lower will be the pole and the center of the circle.

377ᵃ1

And on the shorter days after the fall equinox it is always possible for a rainbow to occur, but on the longer days from one equinox to the other, no rainbow occurs around midday. The cause of this is that all the sections [of the sun's orbit] toward the Bear are greater than a semicircle, and continually become greater than a semicircle [as the sun travels further north], and the invisible part is small; but as for the sections south of the equinox, the section above [the earth] is small, while the section below the earth is big, and the further away it is, the bigger it is, so that in the days around the summer solstice, due to the magnitude of the section, before the H line comes to the middle of the section and to midday, the P line comes to be already completely below, because the midday [sun] is far distant from the earth due to the magnitude of the section. But in the days around the winter solstice, because the sections of the circles are not much above the earth, it is necessary that the opposite occur. For the sun comes to be upon the meridian, when the line on H is raised but a little.

3.6
Parhelia and Rods; Metals and Minerals

One must suppose that the causes of parhelia and rods are the same as those we have discussed.

For the parhelion occurs when the ray of sight is reflected to the sun, while rods occur because the ray of sight that reaches [the sun] is of the sort that, as we said,[111] occurs whenever, the clouds being in the proximity of the sun, the ray of sight is reflected from something wet toward a cloud; for clouds themselves appear uncolored when you look straight at them, but in the water the cloud is full of rods, except that in the latter case the color of the cloud appears to be in the water, while with the rods, the color seems to be on the cloud itself. This comes to be so, whenever the composition of the cloud is irregular, here denser, there rare, and here more watery, there

377ᵇ1

110. Reading O.
111. 374ᵇ9–35.

less so. For when the ray of sight is reflected toward the sun, the shape is not seen, but the color is. And because the bright and white sun, toward which the ray of sight is reflected, appears on something irregular, part appears crimson and part appears green or yellow. For it makes no difference whether one sees the ray of sight through things of this sort or reflected from things of this sort; for either way it appears with the same color, so that if it is crimson one way, it is crimson the other too.

Thus, the rods, because of the irregularity in the mirror, occur not with shape but with color. But the parhelion occurs whenever the air is as regular as possible and evenly dense. That is why it appears white; for the regularity of the mirror produces the single color of its appearance. And the reflection of a concentrated ray of sight, because it reaches the sun altogether from a mist that is dense, that is, one that is not yet rain, but being close to rain, causes the color to appear which belongs to the sun, like the ray of sight that is bent from a smooth bronze surface because of its density. As a result, since the color of the sun is white, the parhelion too appears white. And, for this same reason, the parhelion is more a sign of rain than the rods are; for [in the former case] the air happens to be more favorable for the coming to be of rain. And a southern parhelion more than a northerly, because southern air changes more readily into rain than air toward the Bear.

Both rods and parhelia occur, as we said,[112] around sunset and around sunrise, and neither above nor below [the sun], but at the sides. And they do not occur very near the sun nor very far away either; for the sun dissolves the composition if it is close; and if it is far away, the ray of sight will not be reflected; for when it is stretched out over a long distance from a small mirror, it becomes weak. That is also why halos do not occur opposite the sun. If they occur above and close, the sun will dissolve [the composition]; and if it is far off, the ray of sight will be too small to produce a reflection and will not reach [the sun]. But at the side, the mirror is sufficiently distant that the sun does not dissolve the composition, and the ray of sight arrives [at the sun] in a concentrated mass, because as it travels along the earth, it is not pulled apart, as it would be, if it were spatially moving through open space. But it does not occur below the sun because, near the earth, it would be dissolved by the sun, and if the composition came to be above in mid-heaven, the ray of sight would be pulled apart. Nor does it appear in mid-heaven at all, not even at the sides of the sun; for the ray of sight is not being carried near the earth, so that little reaches the mirror, and the reflected ray becomes altogether weak.

These are pretty much the number and sorts of effects that this segregation presents in the places above the earth. As for the effects that are produced in the earth itself, when [the segregation] is locked up by parts of the earth, these we must discuss.

For [the earth] itself produces two different sorts of bodies because it too has a twofold nature, just as in the area above the earth; for the exhalations are two,

112. 372a10–13.

the vaporous and the smoky, as we claim.[113] And the forms of those things that occur in the earth are twofold as well, the minerals and the metals. When it burns, the dry exhalation is the one that produces all the minerals, like the unmeltable kinds of stones, realgar, ochre, ruddle, sulfur, and the like. The majority of minerals are colored dust, but some are stone from a composition of this sort—for example, cinnabar.

From the vaporous exhalation [originate] all things that are mined, and these are either poured or chased, like iron, gold, and copper. The vaporous exhalation produces all these when it is locked up, and especially in stones, being squeezed together into one and solidified due to the dryness, like dew or frost, whenever it is separated out. But here these things are produced, before they have been separated out. That is why these things are in a way like water, but in a way they are not; for their matter was potentially that of water, but it is no longer, nor do they, like flavors, come to be from water due to some affection. For neither copper nor gold comes to be in this way, but before they become [water], each of them results from the solidification of the exhalation. That is also why they all burn and contain earth; for they contain dry exhalation. Gold alone does not burn. **$378^{b}1$**

We have now spoken about all these things at a general level, and must investigate each one in particular, taking up each kind.

BOOK 4[114]

4.1
Hot, Cold, Wet, and Dry; Putrefaction

Four causes have been distinguished for the elements, and in virtue of the combinations of these, it results that the elements are also four, of which two are capable of affecting, the hot and the cold, and two of being affectable, the dry and the wet. Conviction on these matters is based on induction; for in every case we see hotness and coldness determining, naturally unifying, and changing both things of the same kind and things not of the same kind, and wetting, drying, hardening, and softening them. Things dry and wet, by contrast, both intrinsically and when jointly present in bodies composed of both, are determined, and are affected, by the other affections just mentioned.

113. $341^{b}5$–10.

114. Alexander of Aphrodisias, in his commentary on the *Meteorology*, writes: "The book entitled 'the fourth' of Aristotle's *Meteorology* does belong to Aristotle, but not to the study concerning meteorology. For the things spoken about in it are not proper to meteorology. Rather, as far as the things spoken about are concerned, it would follow *On Coming to Be and Passing Away*" (179.3–6). It is often, with justification, referred to as Aristotle's treatise on chemistry.

Further, it is clear from the accounts by which we define the natures of these; for we speak of the hot and cold as capable of affecting (for the capacity to aggregate is a sort of capacity to affect), but the wet and dry as affectable (for things are said to be easily bounded, and difficult [for other things] to bound, in virtue of their nature being affected in a certain way). [Since all this is so,] it is evident that some things are capable of affecting, others affectable. Having determined these things, we must grasp the workings of these, the workings of the ones capable of affecting, and the forms of the affectable ones.

In the first place, then, universally [speaking], unconditional coming to be and natural change is the work of these capacities, as is the opposite passing away that is in accord with nature. And these occur both in plants and in animals and their parts. Unconditional and natural coming to be is a change due to these capacities (when they stand in the right ratio) in the matter that underlies each nature—this being the affectable capacities we have just mentioned. And the hot and the cold produce [their **379^{a}1** effects] by mastering the matter. But when they fail to master it, partial parboiling, that is, unconcoction, occurs.

But the most common contrary to unconditional coming to be is putrefaction; for all passing away that is in accord with nature is *en route* to it—for example, old age and drying up. Putrescence is the end of all these things, that is, of the ones composed by nature, unless something passes away by force; for it is indeed possible to burn flesh, bone, and whatever, but the end of their passing away in accord with nature is putrefaction. That is why putrefying things become first wet and then, in the end, dry; for they came to be from these, the wet being determined by the dry through the workings of things capable of affecting.

Passing away comes about when what is being determined masters what is determining it because of the environment (although in a special sense putrefying is said of things that partially pass away, when they have been separated from their nature). That is why, indeed, all the others except fire putrefy; for earth, water, and air indeed putrefy; for all these are matter for fire.

Putrefaction is the passing away of the proper and natural heat within a given wet thing caused by an alien heat, that is, the heat from its environment. So, since a thing is affected in this way because of a deficiency of heat, and since everything deficient in this sort of capacity is cold, both would be a cause, and putrefaction would be the common affection of proper coldness and alien heat. For this is also why everything that putrefies becomes dry and, in the end, earth or dung; for as its proper heat leaves it, its natural liquid vaporates with it, and there is nothing to suck in liquid; for its proper heat is what attracts it and draws it in.

Also, a thing putrefies less in cold spells than in warm ones; for in winter the environmental air and water contain little heat, so that it has no strength, while in the summer they have more. Also, what is frozen does not putrefy (for its cold is greater than the air's heat, and hence is not mastered by it, while the mover does master), nor does what is boiling or hot putrefy (for the heat in the air is less than in the

thing, so that it does not master it or produce any change whatever). Similarly too, anything that is moving or flowing putrefies less easily than what is immobile; for the movement due to the heat in the air is weaker than the one preexisting in the thing, so that it does not make it change at all. **379^{b}1**

And due to the same cause, a large quantity putrefies less easily than a small one; for in the larger quantity there is too much proper fire and cold for the capacities in what surrounds it to master it. That is why the sea putrefies quickly when segregated out into parts, but when all together it does not, and all other waters likewise. Also, living things come to be in putrefying things, because the heat being segregated out from them, being natural, causes the composition of the things segregated out.

What coming to be is, then, and passing away, has been stated.

4.2
Concoction and Unconcoction

It remains to state the subsequent forms, the ones that the capacities that were mentioned produce by their workings from things that are already composed by nature as underlying subjects.

Of heat, then, this is concoction (*pepsis*), and of concoction [the forms are] ripening (*pepansis*), boiling (*hepsêsis*), and further, broiling (*optêsis*). Of cold, on the other hand, it is unconcoction (*apepsia*), and of it [the forms are] rawness (*ômotês*), parboiling (*molunsis*), and par-broiling (*stateusis*). We must take it, however, that these names are not said strictly of the things. On the contrary, there are no names established universally for similar things. So we must consider the forms just mentioned as not the same as these things but as of the same sort. However, let us say of each of them what it is.

Concoction, then, is a completion due to the natural and proper heat and is [produced] from the opposing affectables, these being the matter proper to the given thing. For when it has been concocted, it is completed and has come to be. And the starting-point of the completion comes about due to the proper heat, even if certain of the external aids contributed to its accomplishment—for example, nourishment is helped in its concoctions even by baths and by other things of this sort. But the starting-point, at any rate, is the heat within the body itself. And the end in some cases is the nature—but nature, we say, as form and substance. In others the end of concoction lies in a certain underlying shape [or form], as when the wet has come to be of such-and-such quality, or of such-and-such quantity, when broiled or boiled or putrefied, or heated in some other way; for at that time it is useful and we say it has been concocted, like wine must, what gets composed in boils, when pus arises, and tears when they become rheum, and likewise in other cases.

Concoction, in fact, is what everything is affected by when its matter—that is, its liquid—is mastered; for this is what is determined by the heat in its nature. For as

long as the ratio is present in the latter, it is this that constitutes its nature. So things of this sort are signs of health, urine and stool and residues in general. And we say that they have been concocted, because they make clear that the proper heat is mastering the indefinite [matter]. And it is necessary for concocted things to be denser and hotter; for the sort of thing heat accomplishes is to make things more compact, denser, and drier.

This, then, is what concoction is, while unconcoction is non-completion due to a deficiency of proper heat (and deficiency of heat is coldness). And the non-completion is of the opposed affectables, which is for each thing the natural matter.

Let concoction and unconcoction, then, be defined in this way.

4.3
The Various Sorts of Concoction

Ripening is a sort of concoction; for the concoction of the nourishment in fruit is said to be ripening. And since concoction is a completion, ripening is complete when the seeds in the fruit are capable of producing another of the same sort as the fruit itself; for this is also what we mean by "complete" in other cases. In the case of fruit, then, this is ripening, but many other things that have been concocted are said to be ripe, with reference to the same form [of ripeness], but by transference, because, as was said previously,[115] no names have been established for each particular sort of completion having to do with the determinations [of the matter] due to natural heat and cold. In the case of boils, phlegm, and things of this sort, ripening is the concoction of the liquid within them by their natural heat; for it is impossible for what does not master something to determine it. Everything that ripens, then, if it comes from breathy things, is watery; and from things of the latter sort earthen ones are composed; and always from fine-grained things more coarse-grained ones come to be. And in accord with this the nature draws some of these into itself,[116] while others it rejects.

It has been stated, then, what ripening is. Rawness is its contrary; for its contrary is unconcoction of the nourishment in the fruit; and this is the indefinite liquid. That is why rawness is either breathy, watery, or both. And since ripening is a sort of completion, rawness will be an incompletion. Incompletion comes about because of a deficiency of natural heat and a lack of proportion in relation to the liquid that is being ripened. (But nothing wet ripens intrinsically without something dry; for water alone of the liquids does not become coarse-grained.) This lack of proportion results either due to the quantity of the hot being small or because the quantity being determined is large. That is also why the humors of raw things are fine-grained, and cold rather than hot, and they are inedible and undrinkable.

115. 379ᵇ14–18.
116. Reading ἑαυτὴν.

But rawness, in fact, just like ripening too, is said of things in many ways. Thus urine, excreta, and catarrhs are all said to be raw due to the same cause; for raw things are all so called due to the [matter] not having been mastered or composed by the heat. And if we go further, potter's clay is said to be raw and milk and many other things are said to be raw too, if they are capable of changing and being composed by the heat but have remained unaffected. That is why water is said to be boiled, but not raw, because it does not become coarse-grained.

It has now been stated what ripening is, and rawness, and what causes each of them is due to.

Boiling in general is concoction by wet heat of the indefinite [matter] present in the liquid [in the thing being boiled], but the name is said in the strict sense only of things being cooked by boiling. This, as was stated,[117] is either breathy or watery. The concoction comes about due to the fire in the liquid; for what is cooked on griddles is broiled; for it is affected by the external heat and, as for the liquid [that is, the fat] in which it is contained, it dries this up, taking it into itself. But what is boiled produces the contrary effect; for its liquid is segregated out of it due to the heat in the liquid outside it. That is why boiled things are drier than broiled ones; for boiled things do not draw liquid into themselves; the external heat masters the internal; while if a thing's internal heat did master, it would draw liquid into itself.

Not every body can be boiled; for neither can something—for example, stones—in which there is no liquid [to be boiled], nor can things in which there is liquid, but which are too dense for it to be mastered—for example, wood. But those bodies that contain liquid that is affectable by the fire burning in the liquid [outside them] can be boiled. Again, gold, wood, and many other things are said to be boiled, with reference not to this same form, but by transference; for no names have been established for the differences. We also speak of liquids such as milk and grape must as being boiled when the humor in the liquid changes to a certain form due to the heat of the external fire that surrounds them, so that it produces an effect much the same as the boiling just mentioned.

But the end is not the same in the case of all these things, either boiled or concocted. In some, it is with a view to eating, in others, with a view to drinking, in **381^{a}1** others, with a view to some other use, since we speak of drugs too as being boiled.

So all things can be boiled that are capable of becoming more coarse-grained, smaller, heavier; as can those of which some parts are of these sorts, while other parts are of the contrary sorts, because when these things disaggregate some parts become coarse-grained and other parts fine-grained (as milk disaggregates into whey and curd). Olive oil by itself, on the other hand, does not boil, because it is affected in none of these ways.

This, then, is what concoction by boiling is said to be. And it makes no difference whether it occurs in craft-produced instruments or in natural ones, because the cause will be the same in all cases.

117. 380^{a}23–25.

Parboiling is the [sort of] unconcoction that is contrary to boiling. And so the contrary of boiling, and what is called "parboiling" in the primary sense, would be unconcoction of the indefinite [matter] in the body due to a deficiency of heat in the surrounding liquid (that deficiency of heat is presence of cold has already been stated[118]). This comes about because of another sort of movement; for the heat doing the concocting is expelled, and the deficiency of heat is due either to the quantity of cold in the liquid or due to the quantity of it in the thing being boiled; for then the result is that the heat in the liquid is too great to cause no movement at all, but too small to make it even and concoct throughout. That is why things are harder when they are parboiled than when they are boiled, and the wet parts more distinguished.

It has now been stated what boiling is, and what parboiling is, and what cause each is due to.

Broiling is concoction by dry and alien heat. That is why even if someone were to produce a change and a concoction by boiling, but not due to the heat of the liquid but rather that of the fire, when the process is complete, the thing is broiled, not boiled, and if excessively it is said to be burned. And it is due to dry heat when the thing ends up becoming drier. That is also why the outside is drier than the inside, while with boiled things it is the contrary. Also, when the work is artificial, broiling is more difficult than boiling; for it is difficult to heat the outside and the inside evenly. For the parts nearer the fire dry faster and so dry more as well. When, then, the outer ducts contract, the liquid contained in the thing cannot get segregated out, but is trapped inside when the ducts shut.

Broiling and boiling are, of course, due to craft, but, as we said,[119] the same universal forms are also due to nature; for the affections that come about are similar, although they are nameless; for craft imitates nature, since in fact the concoction of nourishment in the body is similar to boiling; for it too comes about in something wet and hot due to the heat in the body. And unconcoction is sometimes like parboiling. Also, it is not in the process of concoction that living things come to be, as some people say,[120] but rather they come to be in the excreta that putrefy in the lower intestines, and then ascend; for concoction takes place in the upper intestines, while the excreta decay in the lower ones. The cause of this has been spoken about elsewhere.[121]

Parboiling, then, is contrary to boiling. And to the concoction we have called "broiling," there is a similarly opposed one, but it is harder to find a name for it. It is the sort of thing that would happen if there were par-broiling but not broiling [proper] because of a deficiency of heat that would take place either because of too little external fire or because of the quantity of water in the thing being broiled; for then the heat is too great to cause no movement at all, but too small to concoct [properly].

What concoction is and unconcoction, ripeness and rawness, boiling and broiling and their contraries, has now been stated.

118. 380[a]8.
119. 379[b]14–17, 380[a]16–18.
120. It is not clear to whom Aristotle is referring—perhaps some Hippocratics.
121. The reference is unclear.

4.4
Wet and Dry

We must now speak about the forms of the affectables, the wet and the dry.

The starting-points of the [elementary] bodies, the affectable starting-points, are wet and dry, and the others are mixtures composed of these, and whichever of them there is more of, of it the nature of the thing is more—for example, some are more dry, others more wet. All of them will, on the one hand, be actual, and, on the other, the opposite—for example, this is how melting stands in relation to meltable.

But since the wet is easily bounded, while the dry is difficult to bound, they are affected by each other somewhat as a gourmet dish is by its seasonings; for the wet is a cause of the dry's being bounded, and each becomes a sort of glue to the other—just as Empedocles puts it in *On Nature*, "gluing meal together with water."[122] And because of this the definite body is composed of both. And of the elements earth **382[a]1** is said to have the most special affections of dry, water of wet. That is why all the definite bodies here are not without earth and water (and whichever it is more of, this capacity is the one each appears to be in accord with), and it is only in earth and in water that there are animals, and not in air or fire, because the former ones are the matter for their bodies.

Among the affections of bodies, the primary ones that of necessity belong to a definite thing are hardness and softness; for it is necessary for what is composed of the wet and dry to be either hard or soft. Hard is that whose surface cannot be pressed into itself; soft is that whose surface can be pressed in, but not by being replaced; for water is not soft; for its surface is not pressed downward by pressure, but is replaced. Something is unconditionally hard or unconditionally soft if it is unconditionally like that, while it is so in relation to something else if it is like that in relation to it. In relation to each other they are undetermined by more or less, but since we discern all perceptibles in relation to perception, it is clear that we determine both the hard and the soft in relation to touch, because it is as a mean that we use touch. That is why we say that what exceeds it is hard and what is deficient is soft.

4.5
Bodies and Solidification

It is necessary for a body that is determined by its own proper defining marks to be hard or soft; for either it can be pressed, or it cannot. Further, it must be solidified; for it is determined by this. So since everything determined and composed is either soft or hard, and softness and hardness are due to solidification, no composed and definite thing could exist without solidification. Solidification, then, must be spoken about.

122. B34 DK.

There are, then, two causes that have to do with[123] the matter, the affecter and the affection—the affecter as where the movement starts from, the affection as form. So solidification and diffusion, drying and wetting, also [involve these]. And the affecter affects due to two capacities and the thing is affected due to two affections, as has been stated.[124] It affects due to heat and cold, and the affection is due either to the absence or presence of heat or cold.

382b1 But since solidification is a sort of drying, we must speak about drying first. What is affected, then, is either wet or dry or composed of both. And we suppose that water is the body of what is wet, and earth of what is dry; for of things that are wet and dry these are the affectable ones. That is also why the cold is more characteristic of the affectable ones; for it is present in them; for in fact we take both earth and water to be cold. And the cold is capable of affecting [only] as destructive or coincidentally, as was said previously;[125] for sometimes the cold is said to burn and heat, not in the way the hot does, but by bringing together and compressing the hot.

Whatever is water, or is a form of water, or contains water, whether brought in or innate can become dry (by "brought in" I mean like the water in wool, by "innate" like the water in milk). Forms of water are things such as the following: wine, urine, whey, and, in general, whatever contains—not due to viscosity—no, or very little, sediment; for sometimes the cause of having no sediment is viscosity, as with olive oil and pitch. All things become dry due either to heating or cooling, but in both cases it is by heat, whether internal heat or external heat; for even things that are dried by cooling, like a cloak, in which the liquid is intrinsically separated, are dried by their internal heat, which makes the liquid evaporate together with it, when, if their wet content is small, the liquid comes out together with the heat as evaporation, due to the surrounding cold.

All things become dry, then, as was said,[126] either by being heated or cooled, and always because of heat, whether internal or external, evaporating the liquid together with it (by "external" I mean, for example, when things are boiled; "internal," when the heat exhales, subtracts, and consumes [the liquid]).

Drying has now been spoken about.

4.6
The Various Sorts of Solidification

Liquefaction is in one case water coming to be by composition, in the other the melting of a solid. Of these, composition occurs when the breath is cooled, while melting will be clear at the same time as solidification.

123. Reading περὶ.
124. 378b12–13.
125. 347b2–7.
126. 382b16–18.

Things that solidify solidify because they are either watery or a mixture of earth and water, and do so due to either dry heat or cold. That is also why all bodies solidified by heat or cold, when they dissolve, dissolve due to their contraries; for those **383^{a}1**
that solidify due to dry heat dissolve due to water, which is wet cold, while bodies that solidify due to cold dissolve due to fire, which is hot. Some things, though, would seem to solidify due to water—for example, boiled honey. But it does not solidify due to the water, but due to the cold within it. 5

Watery things do not solidify due to fire. For they dissolve due to fire, and the same thing in relation to the same thing will not be the cause of the contrary effect in the same thing. Further, it is by the exiting of heat that they are solidified, so it is clear that it is by its entering that they will be dissolved. So it is solidified due to the cold as affecter. That is also why when watery things solidify they do not become 10
coarse-grained; for coarse-grainedness comes about because of the exiting of water, and of the composing of the dry. And water alone of the liquids does not become coarse-grained.

Compounds of earth and water are solidified both by fire and by cold, and become coarse-grained due to both, in some respects in the same way, in others in 15
distinct ways, due to heat drawing out the liquid (for when the liquid evaporates, the dry becomes coarse-grained and composed), or due to cold squeezing out the heat along with which the vaporizing liquid also departs. Things, then, that are soft but not liquid do not become coarse-grained, but rather solidify when water exits them—for example, clay when baked. But mixtures that are liquids become coarse- 20
grained as well—for example, milk. And those that were previously coarse-grained and hard due to the cold often become wet at first, as again clay on first being baked gives off steam and becomes softer (which is why indeed it [sometimes] gets distorted in the kilns). 25

Of the things solidified due to the cold that are compounds of earth and water, but contain more earth, those that solidify because of the exiting of heat melt when the heat enters them again—for example, mud when it has frozen. But those that solidify due to cooling, and because of the evaporation of all their heat at the same time, are indissoluble except by excessive heat, although they can be softened—for 30
example, iron and horn. Wrought iron will indeed melt, so that it becomes liquid and then solidifies again. Steel too is produced in this way; for the dross sinks down to the bottom and is cleared away below. And when it has been affected often in this way and becomes pure, steel results, but they do not do this often because the clearing **383^{b}1**
away involves much waste and loss of weight. But the less the waste, the better the iron. Pyrimachus stone also melts, so that it forms drops and becomes molten, and 5
when it solidifies after it has run, it becomes hard again; and millstones melt, so that they become molten, and when they solidify again, though they are black in color, they become like lime [in consistency].[127] Mud and earth both melt as well.

127. Apparently a sort of silex (especially quartz or flint).

Among things solidified by dry heat, some are non-dissolvable, others dissolvable by a liquid. Pottery and some kinds of stone that are made of earth calcined by fire, such as millstones, are non-dissolvable. But soda and salt are dissolvable in liquid, not in all liquid though, but [only] in cold. That is why they melt in water and in things watery in form, but not in olive oil. For wet cold is contrary to dry heat. If one solidifies, then, the other will dissolve; for in this way contraries will be causes of contraries.

4.7
Coarse-Grainedness Caused by Heat and Caused by Cold

Things that are composed more of water than of earth only become coarse-grained due to fire, while those that are composed more of earth become solidified. That is why soda and salt are composed more of earth, as are stone and clay.

The nature of olive oil, however, is most puzzling. For if it is composed [more] of water, it should be solidified due to cold, but if more of earth, due to fire. But as things stand, it is solidified due to neither, but becomes coarse-grained due to both. The cause is that it is full of air. That is also why it rises to the surface of water; in fact air travels upward too. Cold makes it coarse-grained by producing water from the breath within it. For always, when water and olive oil are mixed, the two together become more coarse-grained. And due to fire and time olive oil becomes coarse-grained and whitens. It whitens due to the evaporation of any water there was within it, while it becomes coarse-grained because, as its heat dies out, water comes to be from the air. In both ways, then, the same affection comes about, and due to the same thing, but not in the same way. It certainly becomes coarse-grained due to both [heat and cold], but it does not become dry due to either (for neither the sun nor cold dry it), not only because it is viscous, but also because it is composed of air. But the water
384ᵃ1 does not get dried out or boiled off due to the fire, because, due to the viscosity, it does not evaporate.

Things that are mixtures of water and earth are fittingly said [to be what they are] in accord with the quantity of each; for a sort of wine becomes both solid and coarse-grained when it is boiled—for example, wine must. In the case of all things of this sort, it is the water that departs when they are drying. A sign that it is the water is that the vapor gets composed into water, if one wishes to collect it. So in those in which something remains, that something is composed of earth. Some of these things, as was said,[128] also become coarse-grained and dried due to cold; for cold not only solidifies, but also dries water, and makes things coarse-grained by making air into water. And solidification, as was said,[129] is a sort of drying.

128. 383ᵃ13–14.
129. 382ᵇ1.

Things, then, that do not become coarse-grained due to cold, but solidified, are composed more of water—for example, wine, urine, vinegar, lye, and whey. But things that become coarse-grained [due to cold] (not by evaporation due to fire) are either composed [more] of earth or are compounds of water and air—for example, honey [more] of earth, olive oil [more] of air. And milk and blood are compounds of both earth and water, but more so of earth in most cases, as too are the liquids from which soda and salt come to be (and stones are also composed of certain ones of this sort). That is why whey, if it has not been separated out, burns off when it is boiled by fire.

Regarding what is earthen [in milk], it also becomes composed due to fig juice, if one boils it in the way doctors do when they curdle it. This is the way the whey and the cheese are separated. But when whey is separated, it no longer becomes coarse-grained but boils off like water. And if milk contains little or no cheese, it is composed more of water and is without nourishment. And blood is similar; for it solidifies when dried by cooling. But the sorts of blood that do not solidify, like that of the deer, are composed more of water, and are cold. Hence, they do not contain fibers; for fibers are composed of earth and are solid. So, when they are removed, the blood does not solidify. This is because it does not become dry; for what remains is water, as with milk when the cheese has been removed. A sign of this is that diseased blood tends not to solidify; for it is serous, [that is,] it is phlegm and water, because of being incapable of being concocted and mastered by the nature.

Further, some of these [compounds of water and earth] are dissolvable—for example, soda; others are indissoluble—for example, pottery. And of these latter, some can be softened—for example, horn; others cannot be softened—for example, pottery and stone. The cause of this is that contraries are a cause of contraries, so that if solidification is due to two, cold and dry, it is necessary for dissolution to be due to hot and wet. That is why dissolution is due to fire and water (for these are contraries): to water, of what is solidified by fire alone, and to fire, of what is solidified by cold alone. So if any things happen to be solidified by both, these are most indissoluble of all. And things become of this sort when, after having been heated, they are solidified by the cold; for the result is that when the exiting heat has evaporated most of their liquid, they are squeezed together again by the cold, so that they provide no entry route even for liquid. And, because of this, neither heat dissolves them (for it dissolves only things solidified by cold) nor water (for it does not dissolve things solidified by cold but only things solidified by dry heat). But iron is melted by heat and solidifies when cooled.

$384^{b}1$

Woods are composed of earth and air. That is why they are combustible, not meltable or softenable, and float on water—except for ebony, which does not; for while the other woods contain much air, in black ebony the air has evaporated out and there is more earth in it.

Potter's clay is composed of earth alone because, while drying, it solidifies by small degrees; for water has no ways in even where breath alone had escaped just by itself, nor has fire; for it solidified the clay.

What solidification is, and melting, and the number of causes they are due to and of things in which they occur, have now been stated.

4.8
The Capacities and Incapacities of Uniform Bodies (1)

From the preceding it is evident that bodies are composed by heat and cold, and are made coarse-grained and solid by the workings of these. And because of being crafted by these, there is heat in all of them, while in some there is also cold, insofar as heat is wanting. So, since these belong [to bodies] due to being capable of affecting, wet and dry due to being capable of being affected, compound bodies have a share of all of them.

The uniform bodies, then, are composed of water and earth, both in plants and in animals, and metals, such as gold, silver, and others of this sort are composed of them and from their exhalation when it is enclosed [under the earth], as has been stated elsewhere.[130]

All these things differ from each other with regard to the special objects of the perceptual modalities, in virtue of their being capable of affecting [the capacities] in a certain way (for a thing is white, fragrant, resonant, sweet, hot, or cold, in virtue of being capable of affecting the perceptual modality in a certain way), and also with regard to other affections more proper to themselves, which are called what they are in virtue of being affectable—I mean, for example, being dissolvable, solidifiable, bendable, and whatever others are of this sort; for all things of this sort are affectables, like wet and dry. It is in virtue of these that bone, flesh, sinew, wood, bark, stone, and each of the other uniform natural bodies differ.

Let us state first the number of these, the ones that are said of things as capacities and as incapacities. They are as follows:

solidifiable (*pêkton*)	non-solidifiable
meltable (*têkton*)	non-meltable
softenable by heat (*malakton*)	non-softenable by heat
drenchable (*tegkton*)	non-drenchable
bendable (*kampton*)	non-bendable
breakable (*katakton*)	non-breakable
shatterable (*thrauston*)	non-shatterable
receptive of impressions (*thlaston*)	non-receptive of impressions
plastic (*plaston*)	non-plastic
compressible (*pieston*)	non-compressible
pullable (*helkton*)	non-pullable

130. 378[a]18–31.

malleable (*elaton*)	non-malleable
splittable (*schiston*)	non-splittable
cuttable (*tmêton*)	non-cuttable
viscous (*glischron*)	crumbly (*psathuron*)
kneadable (*pilêton*)	non-kneadable
combustible (*kauston*)	non-combustible
capable of giving off fumes (*thumiaton*)	incapable of giving off fumes

The majority of bodies, pretty much, differ in virtue of these affections. What sort of capacity each of them has, let us now state.

About solidifiable and non-solidifiable, meltable and non-meltable, we have spoken in universal terms previously,[131] but let us return to them again now. Among bodies that solidify and harden, some are affected in this way due to heat, others due to cold—the one lot due to heat drying liquid, the other lot due to cold squeezing out heat. So one lot is thus affected in virtue of absence of liquid, the other lot in virtue of absence of heat, the watery ones in virtue of absence of heat, the earthen ones in virtue of absence of liquid. The ones affected in this way in virtue of absence of liquid are melted by liquid, unless they are composed in such a way that their ducts are rendered too small for the masses of the water to enter—for example, pottery. Those that are not composed this way are all melted by liquid—for example, soda, salt, and earth out of mud. On the other hand, those solidified by privation of heat are melted by heat—for example, ice, lead, and bronze.

The sorts of bodies, then, that are solidifiable and meltable, and the sorts that are non-meltable, have now been stated.

The non-solidifiable ones are the ones that do not contain watery liquid nor are watery, and are composed of more heat and earth—for example, honey and wine must (for they are as if fermenting); also those in which, though they contain water, there is more air—for example, olive oil, quicksilver, and any that are viscous, such as pitch and birdlime. **385^{b}1**

4.9
The Capacities and Incapacities of Uniform Bodies (2)

Bodies softenable by heat are those solid ones that are not composed of water (as ice is composed of water), but are more earthen, and whose water is neither all evaporated (as in soda or salt) nor possessed irregularly (as in pottery), but are pullable (without admitting water) or malleable (without consisting of water), and softenable by fire—for example, iron, horn, and woods.

131. 4.6–7.

Among bodies that are meltable and of those that are non-meltable, some are drenchable, others non-drenchable—for example, bronze, which is non-drenchable, is meltable, while wool and earth are drenchable; for they become wet through. And bronze, though it is meltable, is not meltable due to water. But some things too, though meltable due to water, are non-drenchable—for example, soda and salt; for nothing is drenchable either that does not become softer when soaked through. Some things, on the other hand, that are drenchable are not meltable—for example, wool and grains. And the drenchable ones are the ones that are earthen and have ducts larger than the masses of water, though they are harder than the [masses of] water.[132] And bodies that have ducts throughout are meltable by water. Why is it, though, that earth is both melted and drenched due to water, while soda is melted but not drenched? Because in soda the ducts are throughout, so that its parts are divided immediately by the water, while in earth, though there are also ducts, they lie so as not to meet, so that the affection differs, depending on which of the two ways it enters.

Some bodies are bendable or straightenable (for example, reed and withy), while other bodies are not (for example, stone and pottery). The ones that are non-bendable and non-straightenable are those bodies whose length is incapable of being changed from being bent to being straight and from being straight to being bent, and bending and straightening consist in the change or movement to being straight or to being curved; for whether a thing is being bent convexly or bent concavely it is being bent. Bending, then, is movement to the convex or to the concave, a thing's length being preserved; for if we were to add "to the straight," a thing would be simultaneously bent and straight—which is precisely what is impossible, for the straight to be bent. And if everything that is bent is either bent convexly or bent concavely, and of these the one is a change to the convex, the other to the concave, there would again not be a bending to the straight, but bending and straightening would be different things. These, then, are the bendable and straightenable things, and the non-bendable and non-straightenable ones.

Some things are both breakable and shatterable, either both at once or separately—for example, wood is breakable but not shatterable, ice and stone are shatterable but not breakable, while pottery is both shatterable and breakable. The difference is that breaking is division and separation into large parts, shattering into parts of random size and into more than two. Things, then, that solidify so that they have many ducts lying so as not to meet, are shatterable (for up to this number they can be divided), and things with ones that stretch a long way, are breakable, while things that have ducts of both sorts are both.

Some things are receptive of impressions, like bronze and wax, while others are non-receptive of impressions, like pottery and water. An impression is a shifting downward of part of a thing's surface by a pushing or a blow, or, in general, by

132. Reading ὄντας δὲ σκληροτέρους.

contact. And such things are either soft,[133] like wax, part of whose surface is shifted while the rest remains the same, or hard, like bronze. Things that are non-receptive of impressions are either hard, like pottery (for its surface cannot be pressed in downward), or wet, like water (for water can be pressed in, but not by a part's being so, but by replacement).

Among things receptive of impressions, the ones that retain the impression and are easily impressible by hand are plastic, while those not easily impressible, like stone or wood, or that, though easily impressible, do not retain the impression, like wool or sponge, are non-plastic, but are compressible.

Compressible things are ones that are capable of contracting into themselves on being pushed, their surface deviating downward without dividing and without one part changing places with another, as happens with water; for it does involve exchange of places. Pushing is a movement due to the mover which comes about due to [continuous] contact. A blow is when [the movement is] from a spatial movement. And things are compressible that have ducts empty of body of the same kind as **386^{b}1** themselves, and are capable—under compression—of compacting into the empty places within them, or rather into their own ducts; for sometimes the ones they contract into are not empty—for example, in a wet sponge (for its ducts are full).[134] But then what the ducts are full of is softer than the thing itself that is naturally such as to compact into itself. Compressible things, then, are ones like sponge, wax, and flesh. Non-compressible ones are ones that are not naturally such as to contract under compression into their own ducts, either because they do not have any or because they have ones filled with things that are harder; for iron is non-compressible, as are stone, water, and every liquid.

Pullable things are ones whose surface is capable of shifting on the sides, since for a thing to be pulled is for its surface to be shifted, while being continuous, in the direction of the mover. And some things are pullable (for example, hair, a leather thong, sinew, dough, and birdlime), others non-pullable (for example, water and stone). Some things indeed are themselves pullable and compressible (for example, wool), others not (for example, phlegm, which is non-compressible but pullable, or sponge, which is compressible but not pullable).

Some things are malleable too (for example, bronze), others non-malleable (for example, stone and wood). The malleable ones are the ones part of whose surface is capable of simultaneously shifting both sideways and downward due to the same blow; things incapable of this are non-malleable. All malleable things are receptive of impressions, but not all things receptive of impressions are malleable (for example, wood). But, generally speaking, the two convert. And of things that are compressible, some are malleable, others not (wax and mud are malleable, wool not).

133. Reading μαλακά.

134. Reading ἐνίοτε γὰρ οὐ κενοί εἰσιν εἰς οὓς συνέρχεται.

Some things are splittable (for example, wood), others non-splittable (for example, pottery). To be splittable is to be capable of being divided beyond the point to which the divider divides; for a thing is split when it divides beyond the point to which the divider divides and in advance of the process of division, while in cutting this is not so. Non-splittable things are the ones that are not capable of being affected in this way. Nothing soft is splittable either (I mean unconditionally soft, not soft in relation to one another; for in the latter way even iron will be soft), nor are all hard things, but only those that are neither liquid, nor receptive of impressions, nor shatterable. And things of this sort are those in which the ducts along which they cohere run lengthwise and not breadthwise.

Cuttable things are hard or soft compositions that are capable, when being divided, of not necessarily splitting in advance of the process of division nor of shattering. And the ones that are not wet are non-cuttable. Some things are both cuttable and splittable—for example, wood. But for the most part things are splittable lengthwise and cuttable breadthwise; for since each is divided into many parts, insofar as the unit is composed of many parts running lengthwise, it is splittable, and insofar as its unity is composed of many parts running breadthwise, it is cuttable.

A thing is viscous when, being wet or soft, it is pullable. And those among bodies which, because of the linking of their parts, are composed like chains are of this sort; for these are capable of much stretching and contracting. And those that are not of this sort are crumbly.

Kneadable things are those compressible ones that retain the compression; non-kneadable ones are either those that are wholly non-compressible or that do not retain the compression.

Some things are combustible, others non-combustible—for example, wood is combustible, as are wool and bone, while stone and ice are non-combustible. Combustible things are the ones that have ducts receptive of fire and liquid in their longitudinal ducts that is weaker than fire. But things that have no ducts or have liquid stronger than fire—for example, ice and very green woods—are non-combustible.

Capable of giving off fumes are those bodies that, though they contain liquid, do so in such a way that it does not evaporate separately when they are treated with burning heat; for vapor is a disaggregation due to burning heat, from liquid into air and wind, capable of wetting things. But fumes[135] can be disaggregated into air due to the passing of time, some drying out as they vanish, others coming to be earth. But this disaggregation is different [from vapor] because it does not wet things nor does it become wind. Wind is a continuous flow of air lengthwise, while fuming is the disaggregation all at once of a compound exhalation of dry and wet due to burning heat. That is why it does not wet things, but rather colors them. The fuming of a woody body is smoke. For I mean to also include bones, hair, and all such things in

135. Reading θυμιάματα.

this same class; for a name common to them has not been established. By analogy, however, they are all in the same class. As Empedocles said:

> Hair, leaves, and birds' thick feathers
> And scales on stout limbs are all the same.[136]

The fumes from fat are a sooty smoke, those from oily material a greasy steam. That is why olive oil does not boil or become coarse-grained, because it is capable of giving off fumes but does not evaporate, while water is incapable of giving off fumes but does evaporate. Sweet wine is capable of giving off fumes, because it is fat, and this produces the same effects as olive oil does; for cold does not solidify it, and it does burn. And though it is named "wine," it does not work like wine; for its flavor is not winey. This is also why it does not intoxicate in the way a random wine does. But it does give off a few fumes, which is why it makes the flames go up.

Combustible bodies seem to be the ones that dissolve into ashes. And all the ones that are solidified due to heat, or by both cold and heat, are so affected; for it is evident that all these are mastered by fire. But of stones, the gemstone called *anthrax*[137] is the least so.

Among the combustible things, some are flammable, others non-flammable, and of the former some can be carbonized. The flammable ones are the ones capable of producing flames, while those that are incapable are non-flammable. The flammable ones are the ones that, while not wet, are capable of giving off fumes. And pitch, olive oil, and wax are more flammable when mixed with other things than by themselves. Most flammable of all are the ones that make smoke go up. Among the ones of this sort, those that contain more earth than smoke can be carbonized.

Further, some meltable things are non-flammable (for example, bronze), some flammable bodies are unmeltable (for example, wood), while some are both meltable and flammable (for example, frankincense). The cause is that the wood has its liquid collected together and continuous throughout the whole, so that it burns out, while bronze has liquid in each part, though it is not continuous and is too little to produce flame. Frankincense, on the other hand, has it both ways.

Among things capable of giving off fumes, the flammable ones are the ones that are non-meltable because they are composed more of earth; for the dry is something they have in common with fire. And when this—the dry—becomes hot, fire is produced. That is why flame is wind or burning smoke. The fumes of wood, then, are smoke, those of wax, frankincense, and things of this sort, those of pitch, and of things containing pitch or the like, are a sooty smoke, while those of olive oil and oily things are a greasy steam. Those of things that burn very badly on their own are also [greasy smoke], because they contain little that is dry, and the change [to fire] is due to this, but do burn quickly together with something else. For the fat is [just] this:

136. B82 DK. Reading λεπίδες.
137. Probably ruby.

the dry oily. Liquids that give off fumes, then, are more wet, like olive oil and pitch, while those that burn are more dry.

4.10
Uniform Bodies

It is by these affections and by these differences, as we have said,[138] that the uniform bodies are distinguished from each other in accord with touch, and further with taste, smell, and color.

By uniform bodies, I mean, for example, metals (bronze, gold, silver, tin, iron, stone, and others of this sort, and those that become segregated out of these) and the ones in animals and plants (for example, fleshes, bones, sinew, skin, visceral body, hairs, fibers, veins), from which the non-uniform parts (for example, face, hand, foot, and others of this sort) are forthwith composed (and in plants, wood, bark, leaf, root, and things of this sort).

But since these are composed by another cause, but the matter of the things of which they are composed is the dry and the wet, that is, water and earth (for each most clearly has each of the capacities), while the affecting ones are the hot and the cold (for these latter produce composition and solidification from the former), let us get hold of which forms of uniform bodies are [composed of] earth, which of water, and which of a compound of them.

Among bodies that have been crafted, some are liquid, some soft, some hard. And of these, the hard ones and the soft ones are due to solidification, as was stated previously.[139]

Liquids that evaporate are composed of water. Those that do not are composed of earth, or of a compound of earth and water (for example, milk), of earth and air (for example, wood), or of water and air (for example, olive oil). And those that become coarse-grained due to heat are compounds. (But of the liquids, wine raises a puzzle. For it both evaporates and becomes coarse-grained, as new wine does. The cause is that wine is not said of only one form of thing, and each behaves differently; for new wine contains more earth than old, and so becomes most coarse-grained due to heat, but solidifies less due to cold; for it also contains much heat and earth. Thus, the wine in Arcadia gets so dried up in its skins due to the smoke[140] that it is scraped off for drinking. If, then, all wine has sediment, it will be composed of either one, earth or water, depending on the quantity of it that it contains.) Liquids that become coarse-grained due to cold are composed of earth. Those that become so due to both cold and heat are compounds of several things—for example, olive oil, honey, and sweet wine.

138. 384b7–385a10.
139. 382a22–27.
140. Reading ὑπὸ τοῦ καπνοῦ.

Among composed things, those solidified due to cold are composed of water (for example, ice, snow, hail, and frost), those solidified due to heat are composed of earth (for example, pottery, cheese, soda, salt), those solidified due to both—and those solidified by cooling, that is, by both a privation of heat and liquid departing with the heat, are of this sort (for salt is solidified by the privation of liquid alone, as are things composed of pure earth, while ice is solidified by the privation of heat alone)—are composed of both water and earth. That is why in fact it is due to both: they contained both.

All those from which all liquid has been evaporated (for example, pottery or amber) are composed of earth; for both amber and the bodies said to be like tears are due to cooling (for example, myrrh, frankincense, and gum; and [river] amber seems to be in this kind, and it solidifies—at any rate, it is evident that animals are enclosed in it, and the heat expelled due to the cold of the river, as with boiled honey when it is dropped into water, evaporates the liquid [in it]). And some of these are non-meltable and non-softenable by heat—for example, amber and certain stones, such as stalactites in caves; for these too come about in the same way, not due to fire but due to the cold expelling the heat, and the liquid coming out along with it due to the heat exiting from the thing, while in the case of the others, it is due to external fire. Those from which the liquid has not wholly evaporated, are composed more of earth, but are softenable by heat—for example, iron and horn. Frankincense and other things of this sort give off vapor in much the same way as wood.

Since things meltable by fire, at any rate, must be put down as meltable, these are mostly composed of water, though some are in fact a compound of water and earth—for example, wax. The ones meltable due to water are composed of earth, the ones not meltable due to either fire or water are composed either of earth or of both earth and water. **389^{a}1**

If, then, all [uniform] things are either liquid or solid, and the ones with the affections just mentioned belong among these, and there is nothing intermediate, all the ones we have mentioned would serve to determine whether a thing is composed of earth, water, or a compound of more than one of them, and whether it is composed due to fire, due to cold, or due to both.

Gold, then, and silver, bronze, tin, lead, glass, and many nameless stones are composed of water; for all these are melted by heat. Further, some wines, urine, vinegar, lye, whey, and serum are composed of water; for all of these are solidified by cold. Iron, on the other hand, and horn, nail, bone, sinew, wood, hair, leaves, and bark are composed more of earth. As, further, are amber, myrrh, frankincense, all the ones said to be tears, stalactites, and crops, such as pulse and corn; for things of this sort are to a greater or lesser extent composed of earth; for some are softenable by fire, while others are capable of giving off fumes and come to be by cooling. As, further, are soda, salt, and the kinds of stone that are neither due to cooling nor are meltable. Blood, on the other hand, and semen, are compounds of earth, water, and air. But blood that contains fibers is composed more of earth (which is why it is solidified by

cooling and melted by liquid), blood that contains no fibers is composed of water (that is why indeed it does not solidify), and semen is solidified by cooling when its liquid exits along with its heat.

4.11
Hot and Cold Liquids and Solids

What sorts of solids and liquids are hot and cold must now be investigated on the basis of what has just been said.

Bodies composed of water are for the most part cold, unless they contain alien heat—as, for example, do lye, urine, and wine. Those composed of earth are for the most part hot, because they are crafted by heat—for example, lime and ashes.

And it must be grasped that the matter is a sort of coldness; for since the dry and the wet are matter (for they are affectable), and of these earth and water are most of all the bodies (for they are determined by cold), it is clear that all bodies composed simply of one of these two elements are more cold, unless they contain alien heat—as, for example, do boiling water and water strained through ashes; for it too contains the heat from the ashes; for in everything that has been burned there is heat, either more or less. That is also why animals come to be in rotten things; for the presence of [alien] heat has destroyed the heat proper to the given thing.

Compound bodies contain heat; for most of them have been composed due to concocting heat, although some are products of putrefaction—for example, the colliquescences. So blood, semen, marrow, fig juice, and all things of this sort are hot as long as they possess their nature, but when they pass away and depart from their nature they are no longer so; for [only] the matter remains, this being earth or water. That is why they seem two ways to people, and some say they are cold, others that they are hot, seeing them to be warm when they are in their natural state, but to solidify when they are separated from it. But though this is the case, nonetheless, as we determined, things in which the matter is mostly water are cold (for water is most of all opposed to fire), while those in which it is mostly earth or air are hotter.

It sometimes happens, however, that the same things become extremely cold and hot due to alien heat; for the solidest and hardest ones are coldest if they are deprived of heat, and most of all cause burning if exposed to fire—for example, water then causes burning more than smoke and stone more so than water.

4.12
Transition to Biology

Since these things have been determined, let us speak in particular about what flesh is, or bone, or the other uniform things; for we grasp what the nature of the uniform

things is composed of, the kinds of them, and which kind each belongs to, through their coming to be; for the uniform things are composed from the elements, and of these as matter all the works of nature are composed.

But while all are composed as from matter from the things just mentioned, as regards substance it is by the account. This is always more clear in the case of the later ones and, in general, of the ones that are like instruments and for the sake of something. For it is more clear that a corpse is a human being homonymously. In the same way, therefore, the hand of a dead man is homonymously a hand, just as stone pipes too might be called "pipes"; for these [bodily parts] also seem to be instruments of sorts. **390^{a}1**

But the cases of flesh and bone are less clearly of this sort, and the cases of fire and water are less clear still; for the for-the-sake-of-which is less clear in those cases where the matter has the greatest extent; for just as, if one wished to take the extreme cases, matter is nothing beyond itself, and substance nothing other than an account, each intermediate thing is in proportion to the closer extreme, since any one of these is also for the sake of something, and is not entirely water or fire, as it is neither flesh nor viscera. And this is still more so in the case of a face and a hand. They are all defined by their work; for those capable of performing their own work are what each of them truly is—for example, an eye if it sees, but when it is incapable of doing so, it is homonymously an eye, like one that is dead or made of stone; for a wooden saw is not truly a saw either, but like one in a picture. It is the same way, therefore, with flesh as well; but the work of it is less clear than that of the tongue.

It is the same way with fire too, although presumably its work is yet less clear from a natural scientific point of view than the work of flesh. And similarly also with the [parts] in plants and inanimate things—for example, bronze and silver; for they all are [what they are] in virtue of a certain capacity to affect or to be affected, just like flesh and sinew. But the accounts of these are not exact, so that it is not easy to see clearly when they are [what they are] and when they are not, unless they have lost their capacity so exceedingly that only their shapes remain—for example, the bodies of ancient corpses suddenly become ashes in their graves, and fruits, when they are exceedingly old, [are fruits] only regarding their shape, though they do not appear to be so regarding their perceptible [taste]. So too with the solids that come from milk. **390^{b}1**

Parts of this sort, then, can come to be by virtue of heat and cold and the movements due to these, since they are solidified by hot and by cold—I mean the uniform ones, such as flesh, bone, hair, sinew, and the like; for these are all distinguished by the differences previously mentioned: elasticity, ductility, fragmentability, hardness, softness, and the others of this sort, all of which come about due to heat and cold and the mixing of their movements. But of the non-uniform parts composed of these—for example, a head, a hand, or a foot—no one could any longer believe this. On the contrary, although cold and heat and movement cause the coming to be of bronze and silver, of a saw, bowl, or box they are no longer the cause. Instead, in their case craft is the cause and in the previous one nature or some other cause.

If we grasp what kind each of the uniform parts is in, we must now get hold of what each of them is—for example, what blood is, or flesh, or seed, as well as each of the others; for we know why each thing is and what it is when we grasp either the matter or the account of their coming to be and passing away, but especially when we grasp both, and also know where the starting-point of movement comes from. And when these parts have been made clear, we must get a theoretical grasp on the non-uniform ones,[141] and in the end the things composed of these—for example, human being, plant, and the others of that sort.

141. *PA* 2–4.

DE ANIMA*

On the Soul

BOOK 1

1.1
Inquiry about the Soul

Since we suppose that knowing is a noble and an estimable thing, and one sort more so than another either in virtue of its exactness or by its being about better and more wondrous things, because of both these things we may quite reasonably place the study of soul in the first rank. It seems too that to truth as a whole, knowledge of the soul makes a great contribution, especially with respect to nature; for the soul is, as it were, a starting-point of living things. **402ª1**

And we are inquiring to get a theoretical grasp on, and to know, both the nature of the soul and its substance, and then as many things as are coincident with it—some of which seem to be special affections of the soul, while others seem to belong because of it to living things as well.

But in every way and altogether it is most difficult to attain any conviction concerning it. For in fact, since the inquiry is also common to many other things—I mean the one about the substance and the what-it-is—it might perhaps seem to someone that a single methodical inquiry is appropriate concerning all the things whose substance we wish to know, just as there is in fact demonstration of the coincidental special affections, so that it is necessary to search for this methodical inquiry. If, however, there is no single and common methodical inquiry concerning the what-it-is, our undertaking will be yet more difficult; for it will be necessary in each case to find out what the way [to inquire] is. But even if it is evident that it is demonstration or division or some other methodical inquiry, there will still be much puzzlement and much confusion as to what to base our inquiry on; for distinct things—for example, numbers and planes—have distinct starting-points.

First of all it is presumably necessary to determine to which of the kinds the soul belongs and what it is—I mean whether it is a this something and a substance or a quality, a quantity, or in some other of the categories that have been distinguished. Further, whether it is a potential being or rather a sort of actuality; for this makes no small difference. Also, it is necessary to investigate whether it has parts or is without parts, and whether all souls are of the same form, and if not of the same form, whether they differ in form or in kind. For, as things stand, people who speak and **402ᵇ1**

* Translated by C. D. C. Reeve. Text: K. Corcilius, *Aristoteles De Anima* (Hamburg, 2017).

inquire about the soul seem to investigate the human soul alone. And one must be careful not to overlook whether there is one account of the soul, as of living thing, or whether there is a distinct account of each (for example, of horse, dog, human, god)—living thing, the universal, being either nothing or posterior. And similarly if there is any other common thing predicated.

Further, if there are not many [sorts of] souls but rather [one sort of soul with] many parts, should one inquire about the whole soul or its parts? Again, it is difficult to determine which of the parts are naturally distinct from each other, and whether one should inquire about the parts first or their works—for example, understanding or the understanding, perceiving or the perceptual part, and similarly in the other cases. And if [we must investigate] the works first, again a puzzle might be raised about whether one should inquire about the corresponding objects before these—for example, the perceptible object before the part that can perceive, and the intelligible object before the understanding part.

It seems that not only is the knowledge of the what-it-is useful for getting a theoretical grasp on the causes of the coincidents connected to the substances[1] (as in mathematics knowing what the straight is and what the curved is, or what a line is and what a plane is, is useful for seeing how many right angles the angles of a triangle are equal to), but also, conversely, knowing these coincidents contributes in great part to knowing the what-it-is; for when we can give an account of these coincidents—of all or of most of them—that is in accord with what appears so, we will then be able to speak best about the substance too; for the starting-point of all demonstration is the what-it-is, so that insofar as definitions [of it] do not lead us to know the coincidents, or fail even to facilitate a likely conjecture about [how to demonstrate] them, it is clear that they have all been stated in a dialectical and empty way.

There is a puzzle too about the affections of the soul, as to whether they are all also shared by what has the soul or whether there is also some affection that is special to the soul itself; for though it is necessary to grasp this, it is not easy. But it appears that in most cases the soul is neither affected by nor does it act without the body (for example, being angry, being confident, having an appetite for things, perceiving in general), while understanding seems to be most of all special to the soul. Yet if it too is a sort of imagination, or does not exist without imagination, it would not be possible even for it to exist without a body.

If, then, some work or affection of the soul is special to it, it will be possible for it to be separated [from the body]. But if there is nothing special to it, it will not be separable, but will be like the straight, to which, insofar as it is straight, many coincidents belong—for example, it will touch a bronze sphere at a point, although, if separated, the straight will not touch it in this way; for it is inseparable, if indeed it always involves some body.

So too the affections of the soul—spiritedness, mild-manneredness, fear, pity, confidence, and further, joy, loving, and hating—would all seem to involve the body;

1. I.e., the intrinsic coincidents.

for at the same time as these, the body is affected in a certain way. This is evidenced by the fact that sometimes, though strong and vivid affections occur [in the soul], it is not provoked or frightened, while at other times it is moved by small and faint ones, as when the body is aroused (*orga[i]*) and its condition is like when one is angry (*orgizêtai*). It is yet more evident that this is so; for sometimes, though nothing frightening is occurring, people come to have the affections of a frightened person.

If this is so, however, it is clear that the affections of the soul are enmattered accounts. So their definitions will be of this sort, for example: "Being angry is a sort of movement of such-and-such a sort of body, or of a part or a capacity, as a result of this for the sake of that." And that is why it already belongs to the natural scientist to get a theoretical grasp on the soul, either all soul or this sort of soul.

A natural scientist and a dialectician, however, would define each of these differently—for example, what anger is. For a dialectician it is "a desire for retaliation" or something like that, while for a natural scientist it is "a boiling of the blood and hot stuff around the heart." Of these, the natural scientist gives the matter, the dialectician the form and the **$403^{b}1$** account. For this is the account of the thing, although it must be in matter of such-and-such a sort if it is to exist. And so of a house the account is this, that it is a shelter to prevent destruction by winds, rain, and heat. But one person will say that it is stones, bricks, and timbers, and another that it is the form in them for the sake of these other things.

Which of these people, then, is the natural scientist? Is it the one concerned with the matter but ignorant of the account, or the one concerned with the account alone? Or is it rather the one concerned with what is composed of both? Who, then, is each of the others? Or is there not someone who is concerned with the affections of the matter that are not separable and insofar as they are not separable? Or is the natural scientist rather the one who is concerned with everything that is a work or affection of this sort of body and this sort of matter? And isn't anything, insofar as it is not of this sort, the concern of someone else, in some cases a craftsman, if there happens to be one, such as a builder or a doctor? And aren't those things that are not separable, but are considered insofar as they are not affections of this sort of body and in abstraction from it, the concern of the mathematician? And insofar as they are separate, that of the primary philosopher?

But let us return to where our account began. We were saying that the affections of the soul are not separable from the natural matter of living things, in just the way, in fact, that things of this sort—spiritedness and fear—are not, and not in the way that line and plane are.

1.2
Movement, Perception, Incorporeality

In our investigation concerning the soul it is necessary to go through the puzzles from which we must become free by going through them first, and at the same time to

gather the beliefs of those of our predecessors who declared any views on the subject, so that we may take what is correct in what they say, and, if anything is incorrect, guard against it.

A starting-point of our inquiry is to set out the things that seem most of all to belong to the soul in accord with nature. What is animate, then, seems to differ from what is inanimate most of all in two regards: moving and also perceiving. And we have also gathered from our predecessors pretty much these two things concerning the soul; for some say that soul is both most of all and primarily what causes movement. And thinking that what was not itself in movement could not possibly move something else, they took the soul to be a thing that is in movement.

404a1 That is what led Democritus to say that the soul is a sort of fire and heat; for the shapes and atoms are unlimited and those that are spherical, he says, are fire and soul—which are like the so-called motes in the air that appear in the sunbeams that come through our windows. The universal seedbed of them, he says, are the elements of the whole of nature; Leucippus says the same. Of those the spherical ones are the soul, because, being of such a shape, they are especially capable of moving through everything and, because they are themselves moving, of moving the rest, on the supposition that the soul is what imparts movement to animals. That is also why they make breathing the defining mark of being alive; for when the surrounding air compresses their bodies, it squeezes out those atomic shapes which, because they are never at rest themselves, impart movement to animals. Then aid comes from outside by the entry of other similar atoms in the process of breathing; for these prevent the squeezing out of those that are already within the animal, helping to counteract what is doing the compressing and solidifying. And living continues just so long as they are capable of doing this.

What the Pythagoreans say seems to contain the same thought; for some of them said that the motes in the air are soul, others that it is what moves them. The reason they spoke in terms of these motes is because they are manifestly in continuous movement, even when it is completely calm. And those who say that the soul is what moves itself tend in the same direction; for all these thinkers seem to have supposed that movement is what most properly belongs to the soul, and that all other things are moved because of the soul, while it is moved by itself; this is because of never seeing a mover that is not itself moving.

Similarly, Anaxagoras says that soul is what moves things, as does anyone else who says that understanding caused the universe to move. But his position is not altogether, at any rate, like that of Democritus. For the latter, soul and understanding are unconditionally the same; for what is true is what appears—which is why (in his view) Homer put it well when he said, "Hector lying there thinking altered thoughts."[2] Democritus, then, does not treat the understanding as a capacity concerned with truth, but says that soul and understanding are the same. Anaxagoras,

2. The reference is to *Iliad* 23.698. The lines refer to Eurylaus, not Hector. See *Met.* 1009b28.

on the other hand, says less perspicuous things about them; for in many places he says **404b1**
that understanding is the cause of what is in a noble and correct way, but elsewhere
that understanding is the soul; for understanding belongs to all living things, great
and small, estimable and less estimable. But understanding—in the sense of wisdom—
appears not to belong in the same way to all animals, not even to all humans. 5

Those, then, who have looked to the movement of what is animate took the soul
to be what is most capable of moving things, while those who looked to knowing
and perceiving beings said that the soul was their starting-points, some positing a
plurality, others one starting-point. Thus, Empedocles says that it is composed of all 10
the elements, each of these also being soul. He says:

> For by earth, we see earth, by water, water,
> By ether, divine ether, but by fire blinding fire,
> By love love, and strife by baneful strife.[3] 15

And in the same way Plato in the *Timaeus*[4] generates the soul from the elements;
for like is known by like, and things are composed of the starting-points. And sim-
ilarly in *On Philosophy*[5] it was determined that the animal-itself is composed of the 20
Form-itself of the one and the primary length, breadth, and depth, and the other
things in the same way. Further, this has also been put in another way: understanding
is the one, scientific knowledge the two (for it proceeds in a single way toward one
thing), belief is the number of the plane, and perception that of the solid. For the
numbers, though they are said to be the Forms themselves and the starting-points, are
nonetheless generated from the elements.[6] And some things are discerned by under- 25
standing, others by scientific knowledge, others by belief, others by perception—and
these numbers are the Forms of things.

On the other hand, since the soul seemed to be both capable of moving things
and, in the way that was mentioned, capable of knowledge, some thinkers[7] generated
it from a combination of both and declared the soul to be a self-moving number. 30

People differ with each other, however, about the starting-points, about what sort
they are and how many they are, especially those who make them corporeal with
those who make them incorporeal, and these with those who mix them and draw **405a1**
their starting-points from both differ. They also differ as to their number; for some
speak of one, others of a plurality. And they consequently differ too in the accounts
they give of the soul; for they not unreasonably took it that the nature capable of
causing movement must be among the primary things. This is what led some to 5

3. B109 DK.
4. 35a–b.
5. The reference is probably to Aristotle's own dialog *On Philosophy*.
6. *Met.* 987^b21–22.
7. E.g., Xenocrates of Chalcedon.

believe that it is fire; for fire is both the most fine-grained and most incorporeal of the elements, and furthermore is moved and also moves other things in a direct way.

Democritus spoke more subtly than others when revealing why [the soul] has each of these characteristics; for soul and understanding are [for him] the same thing, and this is among the primary and indivisible bodies, and its capacity to move things is due to the smallness of its particles and their shape. But of the shapes, the most easily moved, he says, is the spherical, and both the understanding and fire are of this sort.

Anaxagoras, while seeming to speak of soul and understanding as distinct, as we also said previously,[8] treats them both as a single nature, except that he regards understanding above all as, at any rate, the starting-point of everything. At any rate, he says that it alone of the beings is simple, unmixed, and pure. And he assigns both knowing and causing movement to the same starting-point, when he says that understanding set the universe moving.

Thales too, to discern from what is recounted about him, seems to have taken the soul to be something capable of moving things, if indeed he said that a magnet has a soul because it moves iron.

Diogenes, however, as well as some other people, took the soul to be air, thinking that of all things air is composed of the smallest particles and is a starting-point. And that is why the air knows and moves things—insofar as it is a primary thing from which the rest derive, it knows things; and insofar as its particles are the smallest, it moves them.

Also, Heraclitus says that the starting-point is soul, if indeed it is the "evaporation" from which the other things are composed, and furthermore that it is the least corporeal thing and always flowing, and that it is by something moving that something moving is known. And he thinks that the beings are in movement, as most thinkers do.

Alcmaeon too seems to take the soul in much the same way to these; for he says that it is immortal because it resembles immortal things, and that this affection belongs to it because it is always in movement; for divine things too—the moon, the sun, the stars, and the whole heaven—are always in continuous movement.

Among the cruder thinkers, there have been some, such as Hippo, who have declared the soul to be water. They seem to have been persuaded of this from seed, because the seed of all things is wet. For in fact Hippo refutes those who say that the soul is blood, on the grounds that the seed is not blood, and that seed is the primary soul. But others, like Critias, have said the soul is blood. They take perceiving to be what most properly belongs to soul, and that this belongs to it because of the nature of blood. For each of the four elements has found some judge in its favor, except earth. No one declares *it* to be soul, unless there is someone[9] who has said that it is composed of all the elements or is all of them.

8. 404b1–7.
9. 404b11–15.

All, then, define the soul by (one might almost say) three characteristics: moving, perceiving, being incorporeal. And each of these is referred back to the starting-points. That is why those who define it by knowing either make it an element or composed of the elements, all speaking in much the same way as each other, except for one; for like, they say, is known by like; for since the soul knows all things, they let it be composed from all the starting-points. Those, then, who say that there is one cause and one element also regard the soul as one (for example, fire or air), while those who speak of a plurality of starting-points also make the soul a plurality. Anaxagoras alone says that the understanding is unaffectable and has nothing in common with any of the other things. But how, if it is like that, it will know anything and due to what sort of cause, he does not say, nor is it evident from the things he has said.

Those who make contrarieties their starting-points also let the soul be composed from contraries, while those who make one or other of the two contraries such—for example, hot or cold, or something else of that sort—likewise regard the soul too as one of these. That is why they also allow themselves to be guided by the names. Those who pick the hot say that it is also because of this that *to zên* (life) is so named [because *zein* means "to boil"] while those who pick the cold say that it is because of the process of breathing and cooling (*katapsuxis*)—that *psuchê* (soul) is so named.

These, then, are the views about the soul that have been handed down, as well as the causes due to which they are stated in the way they are.

1.3
Soul as a Starting-Point of Movement

First movement must be investigated; for perhaps it is not merely false that the substance of the soul is the sort of thing that it is said to be by those who say that the soul is what moves—or is capable of moving—itself, but rather for movement to belong to the soul is something impossible. **406^{a}1**

That it is not necessary for what moves things to be itself moving was stated previously.[10] For there are two ways in which anything can be moving—either with reference to something else or intrinsically. By "with reference to something else" I mean things that are moving because they are in something that is moving—for example, sailors; for they are not moving in the same way as the ship; for the ship is moving intrinsically, while they are moving because they are in something that is moving. This is clear in the case of the parts [of the body]; for the movement that properly belongs to the feet is walking, and this is also the movement that properly belongs to humans. But it does not belong to the sailors in the present case. Since, then, things are said to be moving in these two ways, we are now investigating about the soul whether it is moving, and participates in movement, intrinsically.

10. 403^{b}30–31.

There are four sorts of movement—spatial movement, alteration, withering, and growth. It is, then, with one or more or all of these that the soul would move. But if it is moved non-coincidentally, there would be a movement that belongs to it by nature, and, if this is so, place will so belong to it as well; for all the sorts of movement that were mentioned occur at a place. But if the substance of soul is to move itself, movement will not belong to it coincidentally, as it does to the pale or three cubits in length; for these are also moved, but coincidentally; for it is what they belong to that is moved, namely, the body. That is also why they have no place belonging to them; but the soul will have a place, if indeed it is by nature that it participates in movement.

Further, if it is moved by nature, it will also be moved by force, and if by force, then also by nature. And it is the same way with rest as well; for what something by nature moves toward, it also rests in by nature. Similarly, what it moves toward by force, it also rests in by force. But what sorts of things forced movements and rests of the soul are, it is not at all easy to give an account of, even if we wished to fabricate one.

Further, if the natural movement of the soul is upward, it will be fire, if downward, earth; for it is to these bodies that these movements belong. The same argument also applies to the intermediate ones.[11]

Further, since it is evident that the soul moves the body, it is reasonable to suppose that it moves it with the same movements with which it is itself moved. But if this is so, then, reversing the order, it is also true to say that the ones with which the body is moved are also the soul's. The body moves with spatial movement, so that the soul too would change in accord with the body, either moving as a whole or with respect to its parts. But, if this is possible, it would also be possible for a soul that had gone out of a body to enter it again, and from this would follow the possibility of the resurrection of animals that have died.

Coincidental movement of the soul may indeed be caused by something else; for an animal may be pushed along by force. But something whose substance included being moved by itself cannot be moved by something else, except coincidentally—just as what is intrinsically good or good because of itself cannot be good because of something else or for the sake of something else. Yet one would say that it is most of all by perceptible objects that the soul is moved, if indeed it is moved at all. But then again if the soul *does* move itself, it would itself also be moved. So if all movement is a displacement of what is moved insofar as it is moved, the soul too must be displaced from its substance, if it does not move itself coincidentally but, rather, movement belongs to its substance intrinsically.

Some people even say that the soul moves the body in the way in which it is itself moved—for example, Democritus, who speaks in much the same way to Philippus, the comic dramatist; for he says that Daedalus made the wooden statue of Aphrodite move by pouring quicksilver into it. Democritus speaks in the same way; for he says that the undivided spheres,[12] which are moving because by nature they can never remain still,

11. I.e., water and air.
12. I.e., the spherical atoms.

draw the whole body after them and so produce its movements. But do these same spheres, we will ask, produce rest as well? How they could do so it is difficult, or even impossible, to say. And, in general, it does not appear to be in this way that the soul moves the animal, but rather through a sort of deliberate choice and understanding.

In the same way, Timaeus[13] gives a natural scientific account of how the soul moves the body; for by its own movement it moves the body as well, because of being woven together with it. For when it had been constituted from the elements and divided into parts in accord with the harmonic numbers, in order that it might have a native perception of harmony and that the universe might move in harmonic revolutions, he bent the straight line into a circle, and, having divided the one circle into two, intersecting at two points, he again divided one of these into seven, the spatial movements of the heaven being regarded as the movements of the soul.[14]

In the first place, to say that the soul is a spatial magnitude is not correct; for by the soul of the universe Timaeus clearly means the sort of soul that is called the understanding (for it certainly cannot be the perceptual soul, or the appetitive soul; for the movement of these is not circular spatial movement). And the understanding is one and continuous in the same way as the activity of understanding, and the activity of understanding as the intelligible objects.[15] These are one by succession, however, just like number, but not like spatial magnitude. That is why the understanding is also not continuous in that way, but either is without parts or continuous in a way different from a continuous magnitude. For how, indeed, could the understanding, if it is a spatial magnitude, even understand anything with any of its parts whatever? It will do so with its parts being regarded either as magnitudes or as points (if a point is even to be called a "part"). If it is with parts regarded as points, since these are unlimited in number, clearly the understanding will never get through them all. If it is with parts regarded as magnitudes, the understanding will understand the same thing many or an unlimited number of times. But it is manifestly possible to do so even once. And if it is enough for it to touch with any of its parts whatever, why should it move in a circle, or have magnitude at all? But if it is necessary for understanding that the whole circle touch its object, what does the touching *by the parts* consist in?

Further, how will what is without parts understand what has parts, or what has parts understand what is without parts? It must be the understanding that is the circle in question; for the movement of the understanding is understanding, while that of a circle is revolution. If, then, understanding is revolution, the understanding would be the circle to which this sort of revolution belongs. What, then, will it always be understanding (for there must be something, if indeed the revolution is eternal)? For although of all practical understandings there are limits (for they are all for the sake of other things), all theoretical ones are determined in a similar way to accounts. But

13. Plato, *Timaeus* 36e.
14. Plato, *Timaeus* 33b–34b. The seven movements referred to are the orbits of the moon, sun, Venus, Mercury, Mars, Jupiter, and Saturn.
15. 430ᵇ14–15, *Sens*. 448ᵇ19–20.

every account is either a definition or a demonstration. And a demonstration is both from a starting-point and has a sort of end: the deduction or the conclusion. But even if they do not terminate, at any rate, they do not return again to the starting-point, but, repeatedly taking middle and extreme terms, proceed in a straight line, while a revolution does bend back again toward the starting-point. Definitions too are all finite.

Further, if the same revolution comes about many times, the understanding must think the same thing many times.

Further, understanding something is more like a coming to rest or coming to a stop than a movement, and it is the same way with a deduction.

But then what is moving not easily but by force is certainly not blessed either. And if movement is not its substance, the soul would be moved against its nature.

On the other hand, the intermixing of the body with the soul without the possibility of release is laborious—more than that, it is something to be avoided, if indeed it is better for the understanding not to be involved with the body, as is customarily said and seems to many people to be so.

Also, the cause of the circular spatial movement of the heaven is unclear [from what Timaeus says]; for the substance of the soul is not the cause of the circular spatial movement (on the contrary, that sort of movement is coincidental to it) and neither is the body (on the contrary, it is rather the case that the soul causes the body's movement).

But then it is not said either why this movement is better. And yet it was supposed to be because of this that the god makes the soul move spatially in a circle, because movement is better for it than remaining at rest, and that this sort of movement better than any other. But since this sort of investigation properly belongs to other accounts,[16] let us leave it aside for now.

There is another absurdity, however, that follows both from this account and from most of the ones concerning the soul; for in fact they attach the soul to a body, and place it in a body, without further determining the cause due to which this attachment comes about or the condition of the body required for it. And yet this would seem to be necessary; for it is because of their association that the one acts, while the other is acted upon, and the one is moved, while the other moves it. None of these relations holds between random things.

These people, however, merely undertake to say what sort of thing the soul is, but about the sort of body that is receptive of it they determine nothing further, as if it were possible, as in the Pythagorean stories, for any random soul to be inserted into any random body; for it seems that each body has its own special form and shape. But what they say is much the same as saying that the craft of building could be inserted into pipes; for while the craft must use its instruments, the soul must use its body.

16. Perhaps those in *Met.* 12.10.

1.4
Soul as a Harmony and as a Self-Moving Number

There is also another belief handed down about the soul, which many find no less plausible than those we have mentioned, and which has given an account of itself—under examination, as it were—in the common accounts too. For its supporters say that the soul is a sort of harmony; for a harmony (they say) is a blend and a composition of contraries, and the body consists of a combination of contraries. And yet, while a harmony is a sort of ratio or composition of the things that are mixed together, the soul cannot possibly be either of these.

Further, a harmony cannot move anything, yet everyone assigns this to the soul as its (one might almost say) chief characteristic. But it is more fitting to speak of **408^{a}1** harmony in connection with health and bodily virtues in general than in connection with the soul. This becomes most evident if we try to assign the affections and works of the soul to some sort of harmony; for it is difficult to make them fit.

Further, if we speak of harmony, we have in view two cases. One, the strictest one, is that of the spatial magnitudes in things that have movement and position, where harmony consists in their being positioned together, whenever they so fit together that nothing of the same kind can intervene; the other is that of the ratio of the things that are mixed together. Neither of the two makes the doctrine reasonable. And if the harmony is the composition of the parts of the body, it makes it very easy to criticize. For the compositions of the parts are many and various. What, then, should one suppose the understanding to be a composition of, and in what way? Or the perceptual part or the desiring part? It is similarly absurd, however, for the soul to be a ratio of the mixture; for the mixture of the elements is not in the same ratio in flesh as in bone. It will follow, then, that a thing has many souls and that they are found throughout the whole body, if indeed all [its parts] result from mixtures of the elements, and the ratio in the mixture is a harmony—that is, a soul.

(One might ask the same question of Empedocles; for he says that each of the parts exists by virtue of some ratio. Is the soul, then, the ratio, or rather, being a distinct thing, does it come about in the parts? Further, is love the cause of any random mixture, or of the one that is in accord with the ratio, and is love the ratio or a distinct thing beyond the ratio?)

These, then, are the sorts of puzzles that arise.

On the other hand, if the soul is something distinct from the mixture, why, then, is the being for flesh and that for the other parts of the animal destroyed at the same time?

In addition to these points, if indeed each of the parts does not have a soul, if the soul is not the ratio of the mixture [in it], what is it that passes away when the soul leaves it behind?

That the soul cannot be a harmony, then, and cannot revolve in a circle is clear from what has been said. But coincidentally it can be moved, as we said,[17] and can move itself—for example, what the soul is in can be moved and it, in its turn, be moved by the soul. In no other way, though, can it possibly be moved with respect to place.

One might more reasonably raise a puzzle about how the soul is in movement, **408b1** though, by looking to the following considerations. For we say that the soul is pained, enjoying, feeling confident, feeling afraid, and further, feeling angry, and also perceiving and thinking. And all these seem to be movements. Hence one might think that the soul itself is being moved. But this is not necessarily so. For even if it is the case that being pained or enjoying or thinking are in the highest degree movements, and that each is a being moved, and that its being moved is due to the soul, as being angry or being afraid is the heart being moved in this way, with thinking being something of this sort or perhaps something else being moved, and these come about in some cases by the spatial movement of certain things with respect to place and in others by their alteration (which ones and in what way is for another account[18])—[even if all that is so,] to say that the soul is feeling angry is like saying that the soul is weaving or building; for it is better, perhaps, not to say that the soul is feeling pity or learning or thinking, but rather that a human being is doing so by means of the soul. And this, not because the movement is in the soul, but because sometimes it reaches as far as the soul, and sometimes begins from it—for example, perception begins from particular things, while recollection begins from the soul and extends to the movements or the traces in the perceptual organs.

The understanding, though, seems to be born in us as a sort of substance, and not to pass away. For if it could pass away, it would most of all be due to the feebleness of old age, but as things stand perhaps it is presumably what happens in the case of the perceptual organs; for if an old man could get such-and-such a sort of eye, he would see as well as a young one does. So old age is not due to the soul's being affected in a certain way but, rather, what the soul is in, as in episodes of drunkenness and disease. And, in particular, understanding—that is, contemplating—are extinguished because something else within passes away, but it itself is unaffectable. For thinking and loving or hating are not affections of it but of this [human being] here that has it, insofar as it has it. That is why when this passes away it neither remembers nor loves; for they were not [affections] of it, but of what is common,[19] which has passed away. But the understanding is perhaps something more divine and is unaffectable.

That the soul cannot be moved, then, is evident from these considerations. But if it cannot be moved at all, clearly it does not move itself.

The most unreasonable of the views mentioned is that which says that the soul is a self-moving number; for its supporters are subject to impossibilities, first, to those

17. 406b5–7.
18. 3.9–10, *MA*.
19. 430a17–25.

that stem from the soul's being moved, and then to the ones special to it, which stem from saying that it is a number. For how is one to understand a unit as being in movement? By what is it moved, and in what way, since it is without parts and without difference? For if it is capable of moving things and of being moved, it must admit of difference. **409a1**

Further, since they say that a line when moved makes a surface, and a point a line, the movements of the units will also be lines; for a point is a unit that has position, and the number of the soul is, of course, somewhere and has position. 5

Further, if one subtracts a number or a unit from a number, another number remains, while plants and many animals, when divided, continue to live and seem to have the same form of soul.

Besides, it would seem to make no difference whether one speaks of units or tiny bodies; for in fact if the tiny spheres of Democritus became points, with only quantity remaining, there will be in it a mover and a moved, just as there is in a spatially continuous thing; for it is not because of a difference in its greatness or smallness that what was mentioned follows, but because it is a quantity. That is why there must be something that will move the units. But if in an animal the mover is the soul, it must also be so in the number [with which the soul is identified], so that the soul will not be the mover *and* the moved but the mover only. How, then, can this possibly be a unit? For it must be different in some way from the other units. But for a point that is a unit, what difference could there be except position? If the units—that is, the points—in the body are distinct [from the units in the soul number], the units will be in the same place as they are; for the unit will occupy the space of a point. And yet what prevents an unlimited number of things from also being in the same place if two can be? For things whose place is indivisible are so themselves. If, on the other hand, the points in the body are the number of the soul, or if the number of the points in the body is the soul, why do not all bodies have a soul? For there seem to be points in all of them—in fact, an unlimited number. 10 15 20 25

Further, how is it possible for the points to be separated and set free from the bodies, if, at any rate, lines do not divide up into points?[20] 30

1.5
Soul as Composed of Elements

The result, as we said,[21] is that in a way this view [that the soul is a number] says the same thing as those who posit that the soul is some sort of fine-grained body, while in another way, like Democritus saying that movement is caused by the soul, it has a special absurdity of its own. For if indeed the soul is present in every part **409b1**

20. Lines here are analogs of souls. See 409a4–7.
21. The reference is presumably to 408a9–11.

of the percipient body, there will necessarily be two bodies in the same place, if the soul is a sort of body. For those, on the other hand, who say that the soul is a number, there will be many points in one point, or every body will have a soul, unless it is of a different sort from the number that comes to exist in the body and is distinct from the points present in it. It also results that the animal is moved by the number in the way that Democritus said something moved it; for what difference does it make whether one speaks of small spheres, large units, or simply spatially moving units? For either way it is necessary for them to move the animal by being themselves moved.

For those, then, who combine number and movement in the same thing these are the consequences, as well as many others of the same sort; for it is not only impossible for something of this sort to be the definition of soul, it cannot even be a coincident of it. And this would be clear if one were to try on the basis of this account to give one of the affections and works of the soul—for example, rational calculations, perceptions, pleasures, pains, and other things of this sort; for, as we said previously,[22] it is not even easy to conjure up one on this basis.

Three ways have been handed down in which people define the soul. Some have declared it to be what is most capable of moving things, since it moves itself; others that it is a body that is the most fine-grained or least corporeal of all. We have pretty much gone through the puzzles and inconsistencies that these involve. It remains to investigate what it means to say that the soul is composed of the elements. For they say this in order that it may perceive the beings and know each of them. But many impossibilities necessarily follow for this account.

For they posit that knowing is of like by like, as if positing that the soul is the things [it knows]. But there are not only these [elements] but also many other things, or perhaps rather an unlimited number, composed of them. As for the things from which each of these is composed, let it be granted, then, that the soul knows and perceives them; but with what will it know or perceive a compound—for example, what god, human, flesh, or bone is? And similarly for any other composite thing; for it is not when in any state whatever that the elements are each of these, but when in a certain ratio and composition, as Empedocles says of bone:

> The pleasant earth in its well-wrought melting pots
> Got two parts of glittering water, out of its eight parts,
> And four of fire; and so white bones were formed.[23]

There is no benefit, then, in the elements being in the soul if the ratios and the composition will not also be present; for each [element] will know its like, but there will be nothing to know bone or human, if these will not also be present. But that this is impossible there is no need to say. For who would raise a puzzle as to whether

22. 408ᵃ4–5.
23. B96 DK.

a stone or a human is present in the soul? Likewise with the good and the not good, and in the same way with other things.

Further, given that things are said to *be* in many ways (for it signifies, on the one hand, the this something and, on the other, quantity, quality, or some other of the categories that have been distinguished), will the soul be composed of all these or not? But there do not seem to be elements common to all of them. Is it composed, then, of the elements of substances and only of them? How, then, will it also know each of the others? Or will they say that there are elements and starting-points special to each kind and the soul is composed of these? It will then be quantity, quality, and substance. But it is impossible from the elements of quantity to compose a substance and not a quantity.

For those, then, who say that the soul is composed of all the elements, these, and others like them, are the difficulties that follow.

It is also absurd to say both that like is unaffectable by like and also that like perceives like and the like knows by like. But they posit perceiving as a sort of being affected and moved, and likewise both understanding and knowing.

And there are many puzzles and difficulties with saying, as Empedocles does, that it is by its corporeal elements that each thing is known, that is, in relation to its like, as what has been said testifies; for the parts of the bodies of animals that are simply earth—for example, bones, sinews, and hair—seem to perceive nothing. So they do not even perceive their like. And yet this is what should properly happen. **410^{b}1**

Further, to each of the starting-points more ignorance than comprehension will belong; for each will know one thing, but be ignorant of many—in fact, of all the others. A consequence for Empedocles, at any rate, is that the god will be the least wise thing of all; for he alone will not know one of the elements, strife, while mortals will know everything, for each is composed of all the elements. And, in general, due to what cause does not every being have a soul, since every one is either an element or composed of one element, or of several, or of all? For it is necessary for one, or some, or all of them to have knowledge.

One might also raise a puzzle as to what exactly it is that makes these one; for the elements seem to be like matter; for the most controlling factor, whatever it is, seems to be what holds them together. But it is impossible that anything should be stronger than the soul and a ruler of it—and yet more impossible in the case of the understanding; for it is reasonable for this to be by nature the most primordial thing and a ruler, while they say that the elements are the first of [all] beings.

All of them, both those who say that because the soul knows and perceives the beings it is composed of the elements, and also those who say that it is the thing most capable of moving, are not speaking about all soul. For not all perceiving beings are capable of moving (for there appear to be certain animals that remain stationary with respect to place, and yet movement with respect to place seems, at any rate, to be the only sort of movement that the soul causes in the animal). It is the same way with those who produce the understanding and the perceptual part from the elements; for

plants manifestly live without sharing in spatial movement or perception, and among animals many do not have thought.

But even if one were to set aside these points and take the understanding to be a part of the soul, and the perceptual part likewise, one would still not, speaking in this way, be speaking in universal terms about all soul or about the whole of any one soul. This is also what happens with the account in the so-called Orphic poems; for it says that the soul, being carried by the winds, enters in from the whole when breathing occurs. But that cannot happen either in the case of plants or in that of some animals, if indeed not all of them breathe; a point that escaped the holders of this view.

Also, if the soul must be produced from the elements, it need not be from all; for one part of a pair of contraries is sufficient to judge both itself and its opposite; for by the straight we know both itself and the crooked; for the standard straightedge is a judge of both, while the crooked is a judge neither of itself nor of the straight.

There are some too who say that the soul is mixed together in the Whole. Presumably that is why Thales thought that all things were full of gods. But this involves certain puzzles. For due to what cause does the soul in air or fire not produce an animal, while in mixtures it does—even though it seems to be of higher quality in the former? (One might also investigate what the cause is due to which the soul in the air is of higher quality and more immortal than the soul in animals.) Both ways an absurdity results and something contrary to reason; for in fact to speak of fire or air as an animal is entirely reckless, and not to speak of them as animals if there is soul in them is absurd.

They seem to assume that the soul is in these [elements], because the whole is the same in form as its parts, so that it is necessary for them to say that the soul too is the same in form as its parts, if it is by a part of the surrounding element being cut off and enclosed in animals that they become living beings. But if the divided part of air [in the animal] remains the same in form, while the soul has non-uniform parts, it is clear that some [part] of soul will be present in it, while some will not. It is necessary, then, either for the soul to be uniform or for it not to be present in any and every part of the universe.

It is evident, then, from what has been said that knowledge does not belong to the soul because the soul is composed of the elements, and that it is not correctly or truly said, either, that it is in movement.

Since, however, knowing does belong to the soul, as well as perceiving and also believing, and furthermore having an appetite for things, wishing, and desires in general, and since movement with respect to place comes about in animals in virtue of the soul, as, furthermore, do growth, prime of life, and withering, one must ask whether each of these belongs to the whole soul—that is, is it with the whole soul that we understand and also perceive and are moved, and, in the case of each of the others, are affected or do things, or distinct ones with distinct parts? And what about life? Does it reside in some one of these, or in several, or in all, or is something else the cause?

Some people say that the soul has parts, and that it understands with one part and has an appetite for things with another. But what exactly is it, then, that holds the soul together, if it by nature has parts? For surely it is not the body, at any rate; for it seems, on the contrary, that it is rather the soul that holds the body together. At any rate, when it departs, the body disperses in vapor and putrefies. If, then, it is something else that makes the soul one, that other thing would be most of all soul. But then we will have to inquire again as to whether it is one or multipartite. For if it is one, why isn't the soul directly one? And if it has parts, the argument will again inquire as to what holds it together, and in this way will go on without limit.

One might also raise a puzzle about the parts of the soul as to what capacity each has in the body. For if the whole soul holds all of the body together, then each of the parts should properly hold together some part of the body. But this seems impossible; for about what part the understanding will hold together, and how it will do so, it is difficult even to fabricate something.

It is evident too that both plants and—among animals—some insects continue to live when divided, as having the same form of soul, even if not numerically the same one; for each of the parts has perception and is moved with respect to place for a certain time. And if they do not continue to do so, there is nothing strange in that; for they do not have the instrumental parts necessary to preserve their nature. But nonetheless in each of the segments all the parts of the soul are present, and they are the same in form as each other and as the whole—as each other, because they are not separable, as the whole soul, because it is divisible. The starting-point in plants also seems to be a sort of soul; for this alone is common to both animals and plants, and it is separate from the starting-point of perception, while nothing has perception without it.

BOOK 2

2.1
First Definition of Soul

So much, then, for the views handed down by our predecessors concerning the soul. **412^a1** Let us go back again and start afresh, as it were, and try to determine what the soul is and what account of it would be most common.

We say, then, that one kind of being is substance, and of this, one sort is as matter, which intrinsically is not a this something, and another is shape and form, on the basis of which something is already said to be a this something, and a third, what is composed of these. And matter is potentiality, while form is actuality—and this in two ways, as scientific knowledge is and as contemplating is.

It is bodies that seem most of all to be substances, and among these, the natural ones; for these are starting-points for the others. Among natural bodies, some have

life, while some do not have it. And by "life" we mean self-nourishment, growth,
15 and decay. So every natural body that participates in life would be a substance, but a substance as a composite is. But since it is also a body of such-and-such a sort, for it has life, the body would not be soul; for the body is not among the things that are predicated of an underlying subject, but instead is as underlying subject and matter.

20 It is necessary, then, for the soul to be substance as form of a natural body that has life potentially. But substance is actuality. Therefore, it is the actualization of such a body. But something is said to be actual in two ways, either as scientific knowledge is or as contemplating is. And it is evident that it is as scientific knowledge is; for both
25 sleep and waking depend on the presence of the soul; and waking is analogous to contemplating, while sleep to having but not activating [scientific knowledge]; and in the same individual scientific knowledge is prior in coming to be. That is why the soul is the first actualization of a natural body that has life potentially.

412b1 This sort of body would be one that is instrumental. And even the parts of plants are instruments, although extremely simple ones—for example, the leaf is a covering for the pod and the pod for the fruit, and the roots are an analog of the mouth; for both take in nourishment.

If, then, one must state something that is common to all soul, it would be that
5 it is the first actualization of a natural instrumental body. That is why one should not inquire whether the soul and the body are one, any more than the wax and the shape, or, in general, the matter of a given thing and that of which it is the matter; for while one and being are said of things in many ways, the strict way is of the actuality.

It has now been stated in universal terms what the soul is; for it is the substance
10 in accord with the account. And this is the essence of this sort of body, just as if one of our instruments—for example, an axe—were a natural body; for its substance would be the being for the axe, and this would be its soul. And if this were separated
15 from it, it would not still be an axe, except homonymously; but as things stand, it is an axe. For it is not of this sort of body that the essence and the account is the soul, but of a certain sort of natural body that has a starting-point of movement and rest within itself.

One must get a theoretical grasp on how what has been said applies also in the case of the parts [of the body]. For if the eye were an animal, sight would be its soul; for that is the substance of an eye, the one in accord with the account. And the eye is
20 matter for sight, and if this fails, it is no longer an eye, except homonymously, like an eye in stone or in a picture. One must now apply what holds in the case of the part to the whole living body; for as the part is in relation to the part, so analogously is
25 the whole of perception in relation to the whole body that is perceptual, insofar as it is such. But it is not what has lost its soul that is potentially such as to live, but what has it; and the seed and the fruit are potentially a body of this sort.

As, then, cutting and seeing, so too is being awake an actuality, and as sight and the capacity of the instrument are, so is the soul, while the body is what is potentially **413a1** [alive]. But just as the eye-jelly plus sight is an eye, so in this case the soul plus the body is an animal.

That the soul, then, is not separable from the body—or that certain parts of it 5 are not, if it naturally has parts—is not unclear; for of some parts [of the soul] the actualization is the actualization of the parts [of the body] themselves. Nonetheless, nothing prevents some of them, at any rate, [from being separable,] because of being the actualizations of no body. Further, it is unclear whether the soul is the actualization of the body in the way a sailor is of a ship.

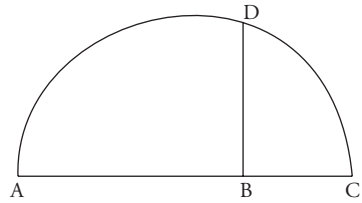
So much, then, by way of making determinations in outline and giving a sketch of the soul. 10

2.2
Second Definition of Soul

Since it is from what is non-perspicuous but more evident that what is perspicuous and better known in accord with its account comes about, one must in this way try again to approach the soul; for the defining account must not only make clear the that, which is what most definitions state, but must also include 15 the cause and make it evident. The accounts of definitions are like conclusions. For example, "What is squaring?" "It is making an equilateral rectangle equal to one that is not equilateral." But such a definition is an account of the conclusion, while the one that states that squaring is the finding of the mean states the cause of the thing.[24]

We say, then, to make a start to the inquiry, that what has soul is distinguished from 20 what lacks soul by living. But things are said to be living in many ways, and we say that a thing is alive even if only one of these is present—for example, understanding, perception, movement and rest with respect to place, further the movement involved

24. Euclid 2.14 shows how to construct a square (or equilateral rectangle) equal in area to a given non-equilateral rectangle. The figure below is the crucial one in the construction:



Here AB and BC are the sides of the given rectangle X. The square on BD is equal in area to X. Euclid 6.13 shows that AB : BD :: BD : BC, making BD the mean, which explains why the square on BD is equal in area to X.

in nourishment, and also both withering and growth. That is why all plants also seem to be alive; for they manifestly have within themselves a capacity and starting-point of this sort, through which they come to grow and decay in contrary directions; for they do not grow upward without growing downward, but grow in both directions alike, indeed in all directions, if they are nourished and continue to live through to the end, as long as they are capable of taking in nourishment.

This [capacity] can be separated from the others, but in the case of mortal beings the others cannot be separated from it. This is evident in the case of plants; for they have no other capacity of soul. It is due to this starting-point, then, that life belongs to all living things, while being an animal is due primarily to perception; for even what does not move or change its place, but which does have perception, is said to be an animal and not just a living thing. The primary sort of perception that belongs to all animals is touch. And just as the nutritive can be separated from touch and every perceptual modality, in the same way touch can be separated from the other perceptual modalities.

The nutritive, we say, is that part of the soul in which even plants share, while all animals manifestly have the perceptual modality of touch. The cause due to which each of these circumstances obtains, we will state later on.[25] For now, though, let this much alone be stated, that the soul is the starting-point of the things mentioned and is defined by these, by the capacities of nourishment, perception, thought, and movement.

But is each of these a soul or a part of a soul, and if a part, is it separable only in account or also in place? Regarding some of them, the answer is not difficult to see, while others involve puzzlement. For just as in the case of plants some manifestly live when divided and [the parts] are separated from each other, since the soul in them is actually one in each plant, but potentially many, in the same way we see this happening with other different sorts of soul in the case of insects that have been cut up; for each part has both perception and movement with respect to place—and if perception, then imagination and desire as well; for where there is perception, there is also both pain and pleasure, and where these, of necessity appetite too. But as regards the understanding and the contemplative capacity, nothing is yet evident, but it seems to be a distinct kind of soul, and it alone seems to admit of being separated, in just the way in which what is eternal is separated from what is capable of passing away.

It is evident from the foregoing considerations, however, that the remaining parts of the soul are not separable, as some people claim;[26] but that they are distinct in account is evident; for the perceptual part and the believing part are distinct, if indeed perceiving and believing are, and similarly for each of the others mentioned.

Further, all of these belong to some animals, some to some, and only one to others, and this produces differences among the animals. What cause this is due to,

25. 434a23–30, b9–24.
26. Plato, *Timaeus* 69c–70e.

must be investigated later on.[27] The situation is much the same as with the [different sorts of] perception; for some animals have them all, others some, others only the one that is most necessary: touch. **414ᵃ1**

Since something is said to be that by which we live or perceive in two ways, as is that by which we know scientifically (for in one way this is scientific knowledge, in another it is the soul, for we say that we know scientifically by each of these), and similarly something is said to be that by which we are healthy [in two ways], in one way by health and in another by a part or even by the whole of the body, and of these scientific knowledge and health are shape and a sort of form or account, and, as it were, activity of the recipient, in the one case of what is capable of scientific knowledge, in the other of what is capable of healing (for the activity of those things that are capable of acting on something seems to occur in that which is affected and suitably disposed), and since the soul is that by which we primarily live, perceive, and think, the result is that it will be a sort of account and a form, and not matter and the underlying subject. For something is said to be a substance, as we said,[28] in three ways, as form, as matter, and as what is composed of both. And of these, the matter is potentiality, while the form is actuality. And since what is composed of the two is an animate thing, it is not the body that is the actualization of the soul, but the soul is the actualization of a certain sort of body.

And that is why those people take things correctly who believe that the soul neither exists without a body nor is a body of some sort; for it is not a body, but it belongs to a body, and for this reason it is present in a body, and in a body of such-and-such a sort—and not as our predecessors supposed, when they inserted it into a body without first determining in which and in what sort, even though not just any random thing appears to be receptive of any random thing. In our way of looking at it, by contrast, it also comes about in accord with reason; for the actualization of each thing naturally comes about in what it already belongs to potentially, that is, in its proper matter.

That the soul, then, is a certain sort of actualization and account of what has the potentiality to be of this sort, is evident from these things.

2.3
The Capacities of Soul

Among the capacities of the soul mentioned, some living things have all of them, as we said,[29] others some of them, and some only one. The capacities mentioned were of nourishment, desiring, perception, movement with respect to place, and thought. To plants only the capacity of nourishment belongs, while to others it belongs together

27. 3.12–13.
28. 412ᵃ7–9.
29. 413ᵇ14–414ᵃ5.

414b1 with the perceptual capacity. But if the perceptual capacity, then so does the desiring one; for desire comprises appetite, spirit, and wish; all animals have at least one sort of perception: touch; but for what has perception there is also pleasure and pain, and the pleasant as well as the painful; and where there are these, there is also appetite; for it is a desire for the pleasant.

Further, animals have a perception of what is nourishing, for touch is a perception of what is nourishing; for all animals are nourished by dry, hot, wet, and cold things, of which the perception is touch. But touch is the perception of the other perceptible objects coincidentally. For neither sound nor color nor odor contribute anything to nourishment, while flavor is one of the tangible objects. Hunger and thirst are appetite—hunger being for dry and hot, thirst for cold and wet. Flavor is a sort of seasoning of these. These must be spoken about perspicuously later on.[30] For now, though, let this much be stated, that to those living things that have touch desire belongs too. But with imagination it is unclear, and must be investigated later on.[31]

Some have in addition to these the capacity of movement with respect to place, while others also have the thinking capacity and also understanding—for example, human beings and anything else there may be that is similar or more estimable.[32]

It is clear, then, that there could be a single account of soul in the same way as there is of figure; for in the latter case there is no figure beyond the triangle and the others that are next in order, and in the former there is no soul beyond the ones mentioned. But, even in the case of the figures, there could be a common account, which will fit all of them, but it will not be special to any figure. Likewise too in the case of the souls mentioned. That is why it is ridiculous to inquire after a common account both in these cases and in others, when it is an account that will not be special to any being, and will not be in accord with its proper indivisible form, to the neglect of the one that is of this sort.

For the situation as regards the soul is much the same as the one concerning the figures; for it is always in what is next in order that what is prior is potentially present, both in the case of figures and in the case of animate things—for example, the triangle in the quadrilateral, and the nutritive capacity in the perceptual one. So one must inquire as regards each given case what the soul of each given one is—for example, what that of a plant is and what that of a human or of a beast.

415a1 And what the cause is due to which they have this order must be investigated. For without the nutritive capacity there is no perceptual one, though the nutritive is separated from the perceptual one in the case of plants. Again, without touch none of the other sorts of perception is present, while touch is present without the others; for many animals have neither sight nor hearing nor perception of odors. And of the ones that can perceive, some have the capacity of movement with respect to

30. 2.10–11.
31. 3.3, 434a1–21.
32. *Cael.* 292a14–22, *NE* 1141a34–b2.

place, while others do not. Finally, and most rarely, they have rational calculation and thought; for among the ones capable of passing away, those that have rational calculation also have all the rest, while of those that have each of the others, not all have rational calculation; on the contrary, some do not even have imagination, while others live by it alone. And concerning the theoretical understanding a distinct account is required.[33]

It is clear, then, that the account concerned with each of these parts is the most appropriate in the case of a soul too.

2.4
The Nutritive Capacity

It is necessary for the one who is going to make an investigation into these capacities to grasp what each of them is, and in this way inquire about the things that follow, and about the others.[34] But if one has to say what each of them is—for example, what the capacity of understanding is, or of perception, or of nourishment—one must further say first what understanding is and what perceiving is; for activities and actions are prior in account to capacities. And if that is so, and further, if prior to them one must get a theoretical grasp on the corresponding objects, then one must, due to same cause, make some determinations about these—for example, about nourishment and perceptible and intelligible objects.

So one must first speak about nourishment and generation; for the nutritive soul belongs to the others as well [as to plants], and it is the first and most common capacity of soul, in virtue of which life belongs to all [living beings], and whose works are generation and the making use of nourishment; for it is the most natural work in those living things that are complete and not deformed or spontaneously generated, to produce another like itself—an animal producing an animal, a plant a plant—in order that they may partake in the eternal and divine insofar as they can; for all desire **$415^{b}1$** that, and it is for the sake of it that they do whatever they do by nature. (But the for-the-sake-of-which is twofold—the purpose for which and the beneficiary for whom.) Since, then, they cannot share in what is eternal and divine by continuous existence, because nothing that admits of passing away can persist as the same and numerically one, they share in it insofar as each can, some more and some less. And what persists is not the thing itself but something like itself, not one in number but one in form.

The soul of the living body is its cause and starting-point. But things are said to be these things in many ways, and the soul is likewise a cause in three of the ways distinguished; for the soul is a cause as that from which movement itself comes, as that-for-the-sake-of-which, and as the substance of animate bodies.

33. 3.4–7.
34. $402^{b}16$–$403^{a}3$.

That it is a cause as substance is clear; for the cause of being for every thing is its substance; living is the being for living things, and the soul is cause and starting-point of this. Further, the actuality is the account[35] of what is potentially. It is evident that the soul is also cause as that-for-the-sake-of-which; for just as the understanding does things for the sake of something, in the same way so does nature, and this is its end. And the soul is this sort of thing in animals in accord with nature; for all natural bodies are instruments of the soul, and just as those of animals are instruments, so too are those of plants, since they are for the sake of the soul. But there are two ways in which something is said to be the for-the-sake-of-which—the purpose for which and the beneficiary for whom. Also, that from which movement with respect to place first derives is soul too; but not all living things have this capacity. And alteration and growth are also in accord with soul; for perceiving seems to be a sort of alteration, and nothing perceives that does not partake of soul. It is the same way as regards growth and withering; for nothing either decays or grows naturally without being nourished, and nothing is nourished that does not have a share in life.

Empedocles did not speak correctly, however, when he added that growth comes about for plants in a downward direction when they root themselves because earth naturally moves spatially in that way, and in an upward direction because fire does likewise. For he does not grasp up and down correctly (for up and down are not the same for all things as they are for the universe,[36] but as the head is of animals, so the roots are of plants, if one must speak of instrumental parts as distinct or the same by appeal to their works). Besides, what is it that holds together the fire and the earth, since they are spatially moving in contrary directions? For they will be pulled apart, if there will be nothing to prevent it. But if there will be something, it is the soul—that is, the cause of growth and nourishment.

But some people think that it is the nature of fire to be the unconditional cause of nourishment and growth; for among the bodies or the elements, fire alone is manifestly something that is nourished and grows. That is why one might suppose that in both plants and animals it is this that does the work. But though it is in a way a contributing cause, it is certainly not an unconditional cause. On the contrary, it is rather the soul that is this; for the growth of fire is unlimited, as long as there is fuel, but there is a limit and an account of size and growth for things that are put together by nature; and these are characteristic of soul but not of fire, and of the account rather than of the matter.

Since the same capacity of the soul is nutritive and generative, one must first make some determinations also about nourishment; for it is distinguished from the other capacities by this work.

Nourishment seems to be a contrary for a contrary—not every contrary for every one, however, but wherever contraries not only come to be, but also grow, from each

35. I.e., the form.
36. *PA* 686ᵃ25–687ᵃ2.

other; for many things come to be from each other, but not all are quantities—for example, the healthy comes to be from the sick. And not even those that do grow from each other appear to nourish each other in the same way—for example, water is nourishment for fire, but fire does not nourish water. It seems, then, that it is especially among the simple bodies that one nourishes and the other is nourished.

But a puzzle arises; for while some people say that like is nourished by like, just as with growth, others think the reverse, as we said,[37] that it is a contrary for a contrary—the supposition being that like is unaffectable by like, while nourishment changes and gets concocted, and in every case change is into the opposite or into the intermediate. Further, the nourishment is affected by the thing being nourished, but not it by the nourishment, just as the carpenter is not affected by the matter, but it by him; the carpenter, for his part, merely changes to activity from inactivity.

But whether the nourishment is the final state of the thing added or the first makes a difference here. And if it is both, but one is unconcocted and the other concocted, it would be possible to speak of it as nourishment in both ways; for insofar as the nourishment is unconcocted, contrary is nourished by contrary, while insofar as it is concocted, like is nourished by like. So it is evident that both parties speak in a way correctly and in a way incorrectly.

But since nothing is nourished that does not partake in life, it is the animate body, insofar as it is animate, that will be what is nourished, so that nourishment is also relative to an animate being—and not coincidentally so. The being for nourishment, however, is distinct from the being for a growth-producer; for it is insofar as the animate thing has some quantity that a growth-producer exists for it, while it is insofar as it is a this something and a substance that nourishment does; for the animate thing preserves its substance and lasts just as long as it is nourished, and it is generative not of what is being nourished, but of something of the same sort as what is being nourished; for its own substance already exists, and nothing generates itself, but rather preserves itself. So this sort of starting-point of the soul is a capacity of the sort that preserves what has it, insofar as it is such, while nourishment equips it to be active. That is why, if deprived of nourishment, it cannot exist. And since there are three things, what is nourished, what it is nourished by, and what nourishes, what nourishes is the primary soul, what is nourished is the body that has it, and what it is nourished by is the nourishment. And since it is right to call everything after its end, and the end is to generate something of the same sort as itself, the primary soul will be one that can generate something of the same sort as itself. But what it is nourished by is twofold, just like what a ship is steered by, both the hand and the rudder—the one causing movement and being moved, the other being moved only. And it is necessary that all nourishment be capable of being concocted, and what effects the concoction is heat, which is why every animate thing has heat.

37. 416^{a}22–24.

What nourishment is has now been stated in outline. But it is necessary to speak perspicuously about this later on in the appropriate accounts.[38]

2.5
Perception

Now that these matters have been determined, let us speak about what is common to all perception.

Perception comes about in being moved and affected, as was said;[39] for it seems to be a sort of alteration. And some people say indeed that like is affected by like. In what way this is possible or impossible, we have said in our universal accounts concerning affecting and being affected.[40]

But a puzzle arises as to why perception of the perceptual modalities themselves does not also take place, and why they do not produce perception without external objects, though present in them are fire, earth, and the other elements, which are [the objects] of perception either intrinsically or of their coincidents.

It is clear, at all events, that the perceptual capacity is not actively, but only potentially so. That is why [it does not perceive without an external object], just as what is burnable does not burn all by itself without something to ignite it; for otherwise it would ignite itself, with no need of a fire existing in actuality. But since we speak of perceiving in two ways (for we say of what is potentially hearing or seeing that it sees or hears, even if it happens to be asleep, and also of what is actively doing so at the time), perception too will be spoken of in two ways—as potential, on the one hand, and as active, on the other. In the same way the perceptible object is also both the potential one and the active one.

First, then, let us speak on the supposition that being affected, being moved, and being active are the same; for, in fact, movement is a sort of activity, although an incomplete one, as was said elsewhere.[41] Everything is affected and moved [in way F] by an agent [F] that is also actively so. That is why, in one way, like is affected by like and, in another, by unlike, as we said;[42] for it is the unlike that is affected, but when it has been affected it is like.

Distinctions, however, must also be drawn concerning potentiality and actuality; for as things stand, we are speaking about them in a simple way. For one way that something can be a scientific knower is the way in which we would say that a human being is a scientific knower because the human being is among the scientific knowers and the ones that have scientific knowledge. Another way is that in which we say that

38. A reference to the lost *On Nourishment*.
39. 410a24–26.
40. *GC* 1.7.
41. *Met.* 1048b29–35.
42. 416a29–b9.

one who already has knowledge of grammar is a scientific knower. Each of these is capable, but not in the same way—the first, because his kind is of the requisite sort, and so is his matter, the other because he is capable of contemplating if he so wishes, and if nothing external prevents him. [In a third way,] there is the one who is already actively contemplating, the one who is actually and in the strict sense a scientific knower of this letter A. Both of the first two, then, are scientific knowers potentially, the one because of having been altered through learning, that is, by frequent changes from the contrary state, the other on the basis of having perception or scientific knowledge of grammar, but not activating it; he [changes] to activity in another way. **$417^{b}1$**

And being affected is not simple either. On the contrary, it is, on the one hand, a sort of destruction of something by its contrary, while, on the other, it is rather the preservation of what is potentially [F] by what is actually [F], and which is like it in the way that a potentiality is like an actuality; for an actual contemplator is what a possessor of scientific knowledge becomes, which is either not precisely an alteration (for the progress of the thing is into itself or into actuality), or else is a distinct kind of alteration. That is why it is not correct to say that what thinks, when it is thinking, is altered, just as it is not correct to say that the builder is altered when he builds. The bringing to actuality, then, of what understands and thinks from doing so potentially should rightly be called not "teaching" but some other name. And a person who learns and acquires scientific knowledge, proceeding from being [a scientific knower] potentially by the agency of one who is actually [a scientific knower], must not be said to be affected, as was said,[43] or else there are two ways of being altered, one a change to conditions of privation, the other to the positive states and the nature [of the thing].

The first change in a perceiver is brought about by the parent, and when it has been born it already has perception, just as it does scientific knowledge. And something is similarly said to be actively perceiving and contemplating. There is the difference, though, that in perception the things productive of the activity are external: what is visible, what is audible, and similarly for the rest of the perceptible objects. The cause of this is that active perception is of particulars, while scientific knowledge is of universals, and these are in a way in the soul itself. That is why it is up to oneself to understand whenever one wishes to, while it is not up to oneself to perceive; for it is necessary that the perceptible object be present. The same holds of the sciences that deal with perceptible objects, and due to the same cause, that perceptible objects are particular and external.

But about these matters there may be an opportunity to speak perspicuously later on.[44] For now, though, let it be enough to have determined this much, that what is said to be potential [or capable] is not simple, but rather while there is what is so in the way we would say that a boy is capable of being a general, there is also what is

43. $417^{a}32–^{b}2$.

44. If the reference is to the way in which contemplation is up to us, it may be to 3.4–5; if it is to the sciences dealing with perceptual particulars, it may be to 3.7, 3.10.

so in the way that a man of the right age is capable of being one, and it is the same way with what is capable of perceiving. But since there is no name for the difference
418a1 between these, although it has been determined about them that they are distinct and in what way they are distinct, it is necessary to use "being affected" and "being altered" as if these names had their prevalent meaning.

What is capable of perceiving is potentially such as the perceptible object already is actually, as was said.[45] It is affected, then, as being not like the object, but when it
5 has been affected it is made like it, and is such as the object is.

2.6
Perceptible Objects

It is necessary to speak first about the perceptible objects of each given perceptual modality. Things are said to be perceptible objects in three ways. Of these, we say that
10 we perceive two intrinsically, and one coincidentally. And of the two, one is special to a given perceptual modality, the other common to all.

By a "special object" I mean whatever cannot be perceived by another perceptual modality, and which we cannot be deceived about—for example, sight is of color, hearing of sound, taste of flavor, while touch has several different ones. At any rate,
15 a given perceptual modality discerns these, and does not make errors about whether there is color or whether there is sound, but rather about what the colored thing is or where it is, or what the thing making the sound is or where it is. Things like these, then, are said to be special objects of a given perception, while those that are said to be common are movement, rest, number, shape, and size; for things like these are special to no perceptual modality but common to all. For a sort of movement is perceived both by touch and by sight.

20 A thing is said to be coincidentally perceptible—for example, suppose the pale thing were the son of Diares; for one perceives this coincidentally, because it is coincident with the pale thing, which one perceives [intrinsically]. And that is why one is not affected at all by the perceptible object insofar as it is of this sort.

Among the intrinsically perceptible things, it is the special objects that are perceptible in the strict sense, and it is to these that the substance of each given perceptual
25 modality is by nature related.

2.7
Sight and Its Objects

That of which there is sight, then, is visible. And what is visible is, on the one hand, color and, on the other, what may be stated in an account, but happens to have no

45. 417a17–22.

name. What we mean will be quite clear as we proceed. For what is visible is color, and it is what is on [the surface of] what is intrinsically visible—intrinsically visible not in account, but because it has within itself the cause of its being visible. And every color is capable of causing movement in what is actively transparent, and this is its **418ᵇ1** nature. That is precisely why it is not visible without light, but rather each color is always seen in light. That is why one must first say what light is.

There is, then, something transparent. And by "transparent" I mean what, though visible, is not intrinsically visible, simply speaking, but rather visible because of the color of something else. Air, water, and many solid bodies are of this sort; for it is not insofar as something is water or insofar as it is air that it is transparent, but because there is a certain nature in it that is the same in both of them and in the eternal body above. And light is the activity of this, of the transparent insofar as it is transparent. And in whatever it is present in, there is potentially also darkness. For light is a sort of color of the transparent, when it is made actually transparent by fire or something of that sort, such as the body above; for something[46] that is one and the same also belongs to it.

What the transparent is, then, and what light is has been stated, that it is not fire nor a body at all, nor an effluence from any body (for it would also be a body in that case), but rather the presence of fire or something of that sort in the transparent; for in addition to its not being possible for there to be two bodies in the same place at the same time, light also seems to be the contrary of dark. But dark is the privation of this sort of state from the transparent, so it is clear again that the presence of it is light.

And so Empedocles is not correct,[47] and nor is anyone else who spoke in this way of light as traveling and extending for a time between the earth and what surrounds it, without our noticing it; for this is contrary not only to what argument makes clear but also to what appears to be so; for over a short distance this might escape our notice, but that it should escape notice all the way from east to west is too much to ask.

It is the colorless that is receptive of color, and the soundless of sound. And the transparent is colorless, and so is the invisible or the scarcely visible—as, for example, the dark seems to be. The transparent is of this sort not when it is actually transparent, but rather when it is potentially so; for the same nature is sometimes darkness and sometimes light.

Not everything is visible in light, but only the color proper to a given thing; for **419ᵃ1** some things are not seen in the light but instead produce perception in the dark—for example, things that appear fiery and shining (there is no one name for them), such as a snuffed wick,[48] horn, and the heads, scales, and eyes of fish. The color special to none of these is seen. The cause due to which these are seen is a subject for another

46. I.e., luminosity.
47. *Sens*. 6.
48. Or possibly a phosphorescent tree fungus (also *mukês*).

account.[49] But for now this much is evident, that what is seen in light is color. This is also why it is not seen without light; for this, as we saw,[50] is what the being is for color, being capable of causing a movement of what is actively transparent; and the activity of the transparent is light. A manifest sign of this is that if one places what has color upon the organ of sight itself, it will not be seen. Instead, the color causes the transparent—for example, the air—to move, and due to this, when the transparent is continuous, the perceptual organ is moved.

For Democritus did not speak correctly about this in supposing that if the intermediate space became a void, an ant would be seen in exact detail even if it were up in the heaven; for this is impossible. For seeing comes about when the part that can perceive is affected in a certain way. But it cannot be affected by the color that is being seen [since it is at a distance]. It remains, then, for it to be affected by what is intermediate, so that there must be something intermediate. If the intermediate space became a void, it is not that things would be seen in exact detail, but rather nothing would be seen at all.

The cause, then, due to which it is necessary for color to be seen in the light has been stated. But fire is seen in both, both in darkness and light, and this is of necessity so; for it is due to this that the transparent becomes transparent.

The same account applies to both sound and odor; for none of these produces perception when it touches the perceptual organ. Instead, due to odor and sound, what is intermediate is moved, and, due to this, each of the perceptual organs. And when one places what makes a sound or has an odor on the perceptual organ, it will produce no perception whatever. The same applies to touch and taste, though it does not appear to. The cause due to which this is so will be clear later on.[51] The medium for sounds is air, for odor something nameless; for there is indeed an affection common to air and water, and as the transparent is to color so this affection, which belongs to both of these, is to what has odor; for aquatic animals also appear to have a perception of odor. But human beings and footed animals that breathe cannot smell without breathing. The cause of these things too will be stated later on.[52]

2.8
Hearing and Its Objects

Now, though, let us first make some determinations about sound and hearing. Sound is twofold; for one is an active sort, the other potential; for we say that some things do not have a sound, for example, sponge or wool, while others do, for example,

49. Aristotle also refers to the phenomenon of phosphorescence at *Sens*. 437b5–7, but his extant treatises contain no account of it.
50. 418b1–2.
51. 422b34–423a2, 423b1–26.
52. 421b13–422a7.

bronze and things that are solid and smooth, because they are able to make sound—that is, to produce an active sound intermediate between themselves and the organ of hearing.

When a sound actively comes about, however, it is always of something, in relation to something, and in something; for a blow is what produces it. That is why indeed it is impossible for a sound to come about when there is [just] one thing; for the thing doing the striking and the thing being struck are distinct. So what makes a sound makes a sound in relation to something. But a blow does not come about without spatial movement, while, as we said,[53] a blow to any random thing is not a sound; for wool produces no sound if it is struck, while bronze does, and things that are smooth and hollow. Bronze does so because it is smooth, while hollow things, by reverberation, produce many blows after the first, because what is moved[, the air inside,] is unable to escape.

Further, sound is heard in air, and in water, although less so. It is not the air or the water that is in control of sound, however, but rather there must be a blow by solid things to each other and to the air. And this happens when air remains after being struck and is not dispersed. That is why if it is struck rapidly and forcefully, it makes a sound; for the movement of the one doing the striking must be too rapid for the air to disperse, just as if someone were to strike a blow to a heap—or rather a whirl—of sand that is in rapid movement.

An echo, on the other hand, comes about whenever, air having become one because a container delimits it and prevents it from being dispersed, the air [outside] is made to bounce back [from it] like a ball. And it seems likely that an echo always comes about, although not a perspicuous one, since what happens in the case of sound is surely just like what happens also in the case of light; for light, in fact, is always reflected (for otherwise there would not be light everywhere, but instead there would be darkness outside the sunlit area), although it is not reflected as it is from water or bronze or anything else that is smooth, so as to produce a shadow, by which we define the light.

What is void is correctly said to be in control of hearing. For the air seems to be a void, and it is this that produces hearing, when it is moved as one continuous thing. But because of its loose texture it does not resound unless what is struck is smooth. And then at the same time it becomes one because of the surface; for the surface of a smooth object is one.

What has a sound, then, is what can cause a movement in air that is one by continuity and that reaches up to [the organ of] hearing. But air is naturally conjoined with the organ of hearing; and because this organ is in air, when the air outside is moved, the air inside is moved. That is why the animal does not hear in every part of it, nor does the air enter every part; for the part that is going to be moved and is animate does not have air everywhere.

53. 419^{b}5–7.

The air alone, then, is soundless because it is easily dispersed; but when it is prevented from being dispersed, its movement is sound. But the air inside the ears has been walled in so as to be unmoving in order that it may perceive in exact detail all the differences in the movement. That is why we hear also in water, because the water does not enter the naturally conjoined air itself. On the contrary, it does not even enter the ear itself, because of the spiral shape. When this does happen, there is no hearing. Nor is there hearing if the eardrum is injured, just as with the cornea of the eye when it is outworn. But it is also a sign of whether there is hearing or not the ear always having an echo, like a horn; for then the air that is in the ears is always moving with a movement that is properly its own. But the sound is alien and not its own. And that is why people say that we hear with what is void and echoing, because we hear with what has the air confined [within it].

Is it what is struck or what does the striking that makes a sound? Or is it in fact both, albeit in distinct ways? For sound is the movement of something that can be moved in the way in which things bounce back from a smooth surface when someone strikes it. Not everything, then, as was said,[54] makes a sound when it is struck or does the striking—for example, if a needle strikes against a needle. On the contrary, what is struck must be even, so that the air may as a single mass bounce back and vibrate.

The differences in things that make sounds are made clear in the sound when it is active; for just as without light colors are not seen, so too without sound the sharp and the dull [are not heard]. Sounds are said to be these, however, by transference from tangible objects; for the sharp moves the perceptual modality a lot in a little time, while the dull moves it a little in a lot of time. Not, of course, that the sharp is rapid and the dull slow, but rather that in the one case, because of the rapidity, the movement comes to be of such a character, and in the other, because of the slowness. **420b1** And it seems that there is some analogy with the sharp and dull in touch; for the sharp, as it were, stabs, while the dull, as it were, pushes, because the one causes movement in a little time, the other in much time, so that it comes about that the one is rapid and the other slow.

About sound, then, let these be our determinations.

Voiced sound is a sort of sound belonging to something animate; for nothing inanimate has a voice, although such things may be said by similarity to have a voice—for example, the pipe, the lyre, and whatever other inanimate things have pitch-variation, melody, and speech. For there is a likeness because voiced sound also has these things. But many animals do not have a voice—for example, those that are bloodless and, among those that have blood, fish. And this is reasonable, if indeed sound is a sort of movement of air. But those fishes that are said to have a voice—for example, those in the Achelous[55]—make a sound with their gills or some other such

54. 419b13–14.
55. *HA* 535b14–18.

part. But voiced sound is sound characteristic of an animal, and not one made by any random part.

But since everything that makes a sound does so because something strikes, strikes something, and in something, and this last is air, it is reasonable that only those things that receive air have a voice. For nature uses what is already breathed in for two works—just as it uses the tongue both for tasting and for speech (of these, tasting is necessary, which is why it also belongs to more things, while communication is for the sake of well-being), so too it uses breath both for the internal heat as something necessary (the cause will be stated elsewhere),[56] and also for voice, so that well-being may be present.

The instrument for breathing is the larynx, and what this part is for the sake of is the lung; for it is due to this latter part that footed animals have more heat than others. And what is first to need the [effects of] breathing is in fact the region around the heart. That is why it is necessary that air should be breathed in and enter.

And so the blow struck on the so-called windpipe by the air that is breathed in, due to the soul in these parts, is voiced sound. For, as we said,[57] not every sound made by an animal is voiced sound (for it is possible both to make a sound with the tongue and as people do in coughing), but what does the striking must be animate, and must involve some sort of imagination. For voiced sound, of course, is a sort of sound that has signification, and is not, like a cough, the sound of the air that is breathed in. Instead, it is with this air that [the animal] strikes the air in the windpipe against the windpipe itself. A sign of this is not being able to use the voice when breathing in or breathing out, but [only] when holding one's breath; for the one holding his breath causes the movement with this. It is evident too why fish are voiceless; for they have no larynx. And they do not have this part because they do not receive air or breath in. The cause of this is for another account.[58]

2.9
Smell and Its Objects

About odor and the smellable it is less easy to make determinations than about the things already discussed; for it is not so clear what sort of thing odor is as it is with sound or color. The cause of this is that this perceptual modality, as we have it, is not exact but is inferior to that of many animals; for a human is a poor smeller and perceives none of the smellable objects unless they are painful or pleasant, because the perceptual organ is not exact. And it is reasonable to suppose that it is also in this way that the hard-eyed animals perceive colors, and that the differences among the colors

56. *Juv.* $474^{a}25$–$475^{b}19$.
57. $420^{b}10$–14.
58. *Juv.* $474^{b}25$–$476^{a}16$, *PA* $669^{a}2$–5.

are not clear to them except insofar as they cause or do not cause fear. And this is the way humankind is with regard to odors.

It would seem, indeed, that while smell is analogous to taste, and similarly the forms of flavor to those of odor, human taste is more exact because it is a sort of touch, and this perceptual modality is most exact in the human being; for in the others he is inferior to many animals, but in touch he is much more exceedingly exact than the rest. That is why it is also the wisest of the animals. A sign of this is that within humankind too being naturally well-disposed or naturally ill-disposed depends on this perceptual organ and on no other; for the hard-fleshed ones are naturally ill-disposed for thought, while the soft-fleshed ones are naturally well-disposed. And just as flavors are sweet or bitter, so too are odors. But some things have an odor and flavor that are analogous, I mean, for example, a sweet odor and a sweet taste, while others have ones that are contrary. In the same way an odor may also be pungent, harsh, sharp, or oily. But, as we said,[59] because odors are not very distinguishable in the way that flavors are, they have taken their names from the latter in accord with a likeness in the things; for sweet odor is from saffron or honey, while pungent odor is from thyme, and the same way in the other cases.

Smell is just like hearing and each of the perceptual modalities in that as hearing is of the audible and the inaudible, and sight of the visible and the invisible, so smell is of what is smellable and what is not smellable. And the smellable comprises what cannot possibly have an odor at all and what has little or faint odor. It is the same way with what is said to be tasteless.

Also, smell comes about through a medium—for example, air or water; for aquatic animals also seem to perceive odor, regardless of whether they have blood or are bloodless, as do those that live in air. And in fact some of them come from a great distance to get their nourishment, guided by odor.

That is why there appears to be a puzzle if, on the one hand, all animals smell in the same way, while, on the other hand, the human being smells when inhaling, and when, instead of inhaling he is exhaling or holding his breath, does not smell (whether the object is distant or near, or even if it is placed on the inside of the nostril); also, if the fact that something placed on the perceptual organ itself is incapable of being perceived is common to all animals, but being incapable of perceiving [odor] without inhaling is special to human beings, as is clear to those who test it; it follows that bloodless animals, since they do not breathe, would have some other perceptual modality beyond those mentioned. But that is impossible, if indeed they perceive odor; for the perception of the smellable, both foul-smelling and sweet-smelling, is smelling. And further they appear to be destroyed as a result of the same strong odors as a human being is—for example, bitumen, sulfur, and the like. They must smell, then, but without inhaling.

59. 421a10–16.

It seems that in human beings this perceptual organ differs from that in the other animals, just as their eyes do from those of hard-eyed animals; for our eyes have eyelids as a protection and a sort of sheath, and if we do not move and open these, we do not see. But hard-eyed animals have nothing of this sort, but see immediately whatever comes about in the transparent. In the same way, then, in some animals the perceptual organ of smell is uncovered, like the eye, while in those that receive air it has a covering, which is removed when they inhale, by dilation of the veins and ducts. And that is why animals that breathe do not smell in water; for it is necessary for them to have inhaled in order to smell, and it is impossible to do this in water. And odor belongs to what is dry, just as flavor does to what is wet, and the perceptual organ of smell is potentially like that.

2.10
Taste and Its Objects

The tasteable is a sort of tangible thing. And that is the cause of its not being perceptible through the medium of a foreign body; for touch [does not perceive that way] either. Also, the body in which the flavor is present—the tasteable—is in what is wet as matter. And this is a sort of tangible thing. That is why, even if we lived in water, if something sweet were thrown in, we would perceive it. But our perception of it would not be through a medium, but would be due to the mixture of it with the wet, as in the case of a drink. Color, by contrast, is not seen in this way, by its being mixed in, nor by effluences. There is nothing, then, serving as medium. And as color is the visible, so flavor is the tasteable. And nothing produces a perception of flavor without wetness, but either actively or potentially it has wetness—for example, the salty; for it dissolves easily and liquefies on the tongue.

Just as sight is of the visible and the invisible (for darkness is invisible but sight also discerns this), and further, of the excessively bright (for this is also invisible, but in another way from darkness), so too hearing is both of sound and silence, of which one is audible and the other inaudible, and of very loud sound as sight is of brightness (for just as a faint sound is inaudible so in a way is a loud or violent one), and as one thing is said to be entirely invisible (as with other cases of impossibility), while another is said to be so if it is natural for it to be visible but it is not visible or slightly visible (just as with the footless and the kernel-less)—so too in that way, then, taste is both of the tasteable and the tasteless, the latter being what has little flavor or slight flavor or is destructive of taste. The drinkable and the undrinkable seem to be a starting-point (for of both there is a sort of taste, in the one case of what is bad and destructive of taste, in the other of what is in accord with nature) and the drinkable is an object common to touch and taste.

But since the tasteable is wet, it is also necessary for its perceptual organ to be neither actually wet nor incapable of being wetted. For taste is affected in some way

by the tasteable, insofar as it is tasteable. What is necessary, therefore, is the wetting of something that is capable of being wetted while being preserved, but which is not itself wet—and this is the perceptual organ of taste. A sign of this is the fact that, when it is very dry, the tongue does not perceive anything nor does it do so when it is very wet; for in the latter case, the tongue becomes wet through the contact with the wetness that is there first, as when someone who has first tasted a strong flavor tastes another, and as to sick people all things seem bitter because they perceive them with a tongue full of bitter wetness.

The forms of flavor, as in the case of colors, are contraries when simple: the sweet and the bitter.[60] And next to the sweet is the oily and to the bitter the salty, and intermediate between these come the pungent, the harsh, the astringent, and the sharp. These seem to be pretty much all the differences in flavor. So what is capable of tasting something is potentially such, while the tasteable is what is capable of making it actually such.

2.11
Touch and Its Objects

As regards the tangible and touch, the same account applies; for if touch is not one perceptual modality but more than one, then the objects that are perceptible by being tangible must also be of more than one sort. But there is a puzzle about whether it is more than one or one, and about what the perceptual organ of the capacity of touch is, whether it is flesh, and what is analogous to this in other beings, or whether it is not, but instead this is the medium, while the primary perceptual organ is something else that is internal. For every perceptual modality seems to deal with one sort of contrariety—for example, sight with white and black, hearing with high and low pitch, and taste with bitter and sweet. But in the tangible there are many sorts of contrariety—hot cold, dry wet, hard soft, and whatever others are of this sort.

But there is a sort of resolution, at any rate, to this puzzle, that with the other perceptual modalities too there is more than one sort of contrariety—for example, in voiced sound there is not only high and low pitch, but also loudness and softness, smoothness and roughness of voice, and others of this sort. And there are other differences of this sort also in the case of color. But what the one thing is that is the underlying subject for touch in the way that sound is for hearing is not clear.

As to the question of whether the perceptual organ is internal or not, but is instead **423a1** immediately the flesh, it seems to be no sign of this that the perception comes about at the same time as contact does. For even as things stand, if one were to make a sort of membrane and stretch it around the flesh, this would immediately on being touched report the perception in the same way. And yet it is clear that the perceptual

60. *Sens.* 442a12–13.

organ is not in this membrane. And if it were in fact to become naturally conjoined [with the flesh], the perception would pass through even more quickly. That is why this sort of part of the body seems to have the same character as air would have if it were naturally conjoined with us all around; for then we would have seemed to perceive sound, color, and odor with one thing, and sight, hearing, and smell to be one perceptual modality. But as things stand, because what the movements pass through is discontinuous with us, it is evident that the perceptual organs that were mentioned are distinct.

But in the case of touch, as things stand, this is unclear; for the animate body cannot be composed of air or water; for it must be something solid. It remains, then, for it to be mixed from earth as well as from these, as flesh and what is analogous to it tend to be. So it is necessary for the body too to be the naturally attached medium for the capacity of touch, through which the perceptual modalities—though more than one—do operate. That they are of more than one sort is made clear by touch in the case of the tongue; for it perceives all tangible objects with the same part as it does flavors. If, then, the rest of our flesh also perceived flavor, taste and touch would have seemed to be one and the same perceptual modality. But as things stand they are two, because they are not interchangeable.

But someone might raise the following puzzle. If every body has depth, and this is the third dimension, and if intermediate between two bodies there is a third body, then it is not possible for the two to touch each other. But what is wet is not without body, neither is what is wet on the surface, but it must either be water or contain water. And things that touch each other in water, since their extremities are not dry, must have water intermediate between them, with which their extremities are flooded. But if this is true, then it is impossible for one thing to touch another in water. And it is the same way in air too (for air stands to the things in air as water does to the things in water, but this more escapes our notice, just as it more escapes the notice of aquatic animals whether the things that touch each other are wet). The question is, then, whether the perception of all objects comes about in **423^{b}1** the same way, or that of distinct things in distinct ways, just as it now seems that taste and touch perceive by touching, while the other perceptual modalities do so from a distance.

But this is not the case. On the contrary, we perceive even what is hard and what is soft through other things, just as we do what is productive of sound, what is visible, and what is smellable. But the latter are further away, the former close at hand, which is why it escapes our notice, since we do indeed perceive all things through a medium, but in these cases it escapes our notice. And yet, as we also said previously,[61] even if we perceived all the tangible objects through a membrane without noticing that it intervened, we would be in the same position as we now are in water and in air; for it seems to us now that we touch the things themselves and nothing through a medium.

61. 423^{a}2–5.

But there the tangible differs from what is visible and what can produce a sound, in that we perceive the latter because the medium acts on us in some way, while we perceive what is tangible not as a result of the medium but rather at the same time as the medium, like a man who is struck a blow through his shield; for it is not that the shield having been first struck then strikes the man a blow, but rather what happens is that both are struck at the same time.

In general, then, it seems that as air and water are to sight, hearing, and smell, so the flesh and the tongue are to their perceptual organ as each of these is. And when the perceptual organ itself is touched, neither in the one case nor in the other can perception take place—for example, if someone were to place a white body on the surface of the eye. From which it is also clear that what can perceive the tangible is internal. For it would be precisely like what happens in the case of the other perceptual modalities; for things placed on the perceptual organ are not perceived, but what is placed on the flesh is perceived; so the flesh is the medium of what can perceive by touch.

It is the differences in body insofar as it is body that are tangible objects. I mean the differences that determine the elements, hot, cold, dry, and wet, about which we spoke previously in our account of the elements.[62] The perceptual organ for these, the one that can perceive by touch and in which the perceptual modality called "touch" primarily belongs, is the part that is potentially such as they are; for perceiving is a sort of being affected, and so what does the affecting makes that part such as it is actively, the part being such potentially. That is why we do not perceive what is equally as hot, cold, hard, or soft [as the perceptual part], but only the excesses, the perceptual modality being a sort of mean between the contraries in the perceptible objects. And that is why it discerns the perceptible objects. For the mean is capable of discerning; for in relation to each extreme it becomes the other. And just as what is to perceive white and black must be neither of them actively, although both potentially (and similarly too in the case of the other perceptual modalities), so in the case of touch it must be neither hot nor cold.

Further, just as sight, as we saw,[63] was of the visible and in a way of the invisible, and just as the rest of the perceptual modalities too were similarly of opposites, so touch is of the tangible and the intangible—where the intangible consists of what has to an altogether minor degree the differences present in tangible objects, as is the case with air, and of the excessive tangible things, such as those that are destructive [of the perceptual modality].

Each of the perceptual modalities has now been spoken about in outline.

62. *GC* 330ᵃ30–ᵇ7.
63. 422ᵃ20–21.

2.12
Perception as the Capacity to Receive Form without Matter

Speaking in universal terms about every perceptual modality, one must grasp that the perceptual modality is what can receive the perceptible forms without the matter, as wax receives the seal of the signet ring without the iron or the gold; it takes on a golden or brazen seal of a signet ring, but not insofar as it is gold or bronze. In the same way too the perceptual modality for each [sort of object] is affected by what has color, flavor, or sound, but not insofar as each is said to be [what it is], but insofar as it is of such-and-such a sort, and in accord with the ratio.[64] The primary perceptual organ is that in which a capacity of this sort exists. It is the same [as the capacity], but the being [for them] is distinct; for what does the perceiving would be a spatial magnitude; but surely neither the being for what is capable of perceiving nor the perceptual modality is a spatial magnitude, but rather a sort of ratio and capacity of that thing.

It is evident from this why exactly it is that the excesses in perceptible objects destroy the perceptual organs; for if the movement is too strong for the perceptual organ, the ratio is dissolved (and this, as we saw,[65] is the perceptual modality), just as the consonance and pitch [of a lyre] are if the strings are struck too forcefully.

And it is also evident why exactly it is that plants do not perceive, although they have a part that is soul and are affected by tangible objects; for in fact they are cooled and heated; for the cause of this is their not having a mean, nor a starting-point of a sort that can receive the forms of perceptible objects; on the contrary, they are affected [by these objects] along with the matter.

But someone might raise a puzzle as to whether what is incapable of smelling can be affected in any way by odor, or what is incapable of seeing by color, and similarly in the other cases. But if the smellable is odor, if it produces anything, it is smelling that odor produces. So none of those things that are incapable of smelling can be affected by odor (and the same account applies in the other cases), nor can any of the ones that are capable, except insofar as each is capable of perceiving [the relevant thing]. At the same time, this is also clear from the following. It is not light and dark or sound or odor that produces any effect on bodies, but rather it is the things in which these perceptible objects are present—for example, it is the air that accompanies the thunder that splits the wood. Tangible objects and flavors, on the other hand, do affect bodies. For otherwise what would inanimate things be affected and altered by? Will these other objects, then, produce some effect? Or is not every body affected by smell and sound, and are those that are affected indeterminate and such as not to remain where they are—for example, air (for air gives off odor as if it had been affected)? What then is smelling beyond

64. $426^{a}27–^{b}9$.
65. $424^{a}24–25$.

some sort of being affected? Or is smelling perceiving, while the air, when affected, quickly becomes perceptible?

BOOK 3

3.1
Why There Are No More Than Five Perceptual Modalities

That there is no perceptual modality beyond the five (I mean by these sight, hearing, smell, taste, and touch), anyone may be persuaded from the following considerations. For if even, as things stand, of everything for which touch is the perceptual modality we indeed have perception (for all the affections of the tangible insofar as it is tangible are perceptible to us by touch); and if indeed when we lack any perceptual modality we must also lack some perceptual organ; and if all the things that we perceive by touching them ourselves are perceptible by touch, which is a perceptual modality we in fact have, while all those we perceive through media without touching the things themselves we perceive by means of the simple bodies (I mean, for example, air and water); and if it is the case that more than one perceptible objects that are distinct in kind from each other are perceived through one [simple body], then a being possessed of a perceptual organ of this sort must be capable of perceiving both (for example, if the perceptual organ is composed of air, and air is the medium for both sound and color), while if there is more than one medium for the same perceptible object (for example, air and water for color, since both are transparent), then even a being possessed of [a perceptual organ composed of] only one of them will perceive whatever is perceptible through both; and if perceptual organs are composed of two of these simple bodies only, air and water (for the eye-jelly is composed of water, the organ of hearing of air, and the organ of smell of one or the other of these), while fire either belongs to none or is common to all (for nothing is capable of perceiving without heat), and earth either belongs to none or is most of all a constituent especially connected to touch; then it would follow that there is no perceptual organ outside those composed of water and air, and these some animals possess even as things stand, with the result that all the perceptual modalities are possessed by those animals that are not either incomplete or deformed (for it is evident that even the mole has eyes under its skin); so if there is not some other [simple] body or some affection possessed by none of the bodies that exist here, then no perceptual modality will be left out.

But neither, however, can there be some special perceptual organ for the common perceptibles, which we [then] perceive coincidentally by means of each perceptual modality—for example, movement, rest, shape, magnitude, number, and oneness;

for we perceive all these by movement (for example, magnitude by movement, and so also shape, for shape is a sort of magnitude, rest by non-movement, number by negation of continuity) and by the special objects (for each perceptual modality perceives one [of these]). So it is clear that it is impossible for there to be a special perceptual modality for any of these—for example, for movement; for in that case it would be the way it is now when by sight we perceive the sweet; and this we do because we happen to have perceptual modalities for both [color and sweetness], by which, when they occur together, we know them simultaneously; otherwise, we would perceive them in no other way than coincidentally—for example, [we perceive] the son of Cleon, not because he is the son of Cleon, but because he is pale, and this pale thing coincides with the son of Cleon. But for the common perceptibles we already have a perceptual capacity that is common, not coincidentally. There is, therefore, no special perceptual modality [for them]; for otherwise we would perceive them in no other way than in the way just mentioned that we see the son of Cleon.

The perceptual modalities, however, perceive each other's special objects coincidentally, not insofar as they are the perceptual modalities they are but insofar as they are one, whenever the perception comes about at the same time in relation to the same thing—for example, that bile is bitter and yellow (for it is certainly not for any *other* perceptual modality to state that both are one). That is also why we may be deceived, and if something is yellow, we may think that it is bile.

For the sake of what, one might inquire, do we have several perceptual modalities instead of only one? Or is it in order that the accompanying common perceptibles should less escape our notice—for example, movement, magnitude, and number? For if there was sight alone, and it was of white, they would more escape our notice, and all things would seem to be the same because of color and magnitude accompanying each other at the same time. But as things stand, since the common perceptibles belong in the objects of another perceptible capacity as well, this makes it clear that each of them is something distinct.

3.2
Perceiving That We Perceive; Relation of Perceptual Modalities to Their Objects; Distinguishing These Objects

Since we perceive that we see and hear, it must either be by sight that someone perceives that he sees or by another [perceptual capacity]. But then it will be the same one that perceives sight and the underlying color. So either there will be two modalities perceiving the same thing, or else one will perceive itself. Further, if the perceptual modality perceiving sight were indeed a distinct one, either they will go on without limit or there will be one that perceives itself. So one should grant this to the first perceptual modality.

But this involves a puzzle; for if to perceive by sight is to see, and what is seen is color or what has color, then if someone is to see the thing that sees, the primary thing that sees will also have color. It is evident, therefore, that to perceive by sight is not one thing; for even when we do not see, we discern darkness and light by sight, although not in the same way. Further, even the thing that sees is in a way colored; for each perceptual organ is receptive of the perceptible object without the matter. That is why, even when the perceptible objects are gone, perceptions and appearances remain in the perceptual organs.

The activity of the perceptible object and of the perceptual modality are one and the same (although the being for them is not the same). I mean, for example, the active sound and the active hearing; for it is possible to have hearing and not to hear, and what has a sound is not always making a sound. But when what can hear is active and what can make a sound is making a sound, then the active hearing comes about at the same **426ᵃ1** time as the active sound, and one might say that the one is a hearing and the other a making of a sound. If, then, the movement—that is, the making and the being affected—is in the thing being acted upon, then both the active sound and the active hearing must be in what is potentially hearing; for the activity of what produces and of what causes movement comes about in the thing that is affected. That is why it is not necessary for what moves something to be itself moved. The activity of what can make a sound, then, is a sound or a making of a sound, while that of what can hear is hearing or an act of hearing; for hearing is twofold, and sound is twofold.

The same account also applies to the other perceptual modalities and perceptible objects. For just as the acting and the being affected are in what is being affected and not in what is acting, so both the activity of the perceptible object and of the perceptual modality are in the perceptual modality. But in some cases they are named, for example, the making of a sound (*psophêsis*) and the act of hearing (*akousis*), while in other cases one or the other is nameless; for the activity of sight is said to be seeing (*horasis*), while that of color is nameless, and that of taste is tasting (*geusis*), while that of flavor is nameless.

Since there is one activity of the perceptible object and of the perceptual modality, although their being is not the same, it is necessary for hearing and sound that are said to be such in this [active] way to be destroyed and to be preserved together, and so also with flavor and tasting, and similarly with the others. But when these are said to be such potentially this is not necessary.

The earlier natural scientists, however, did not speak well about this, since they thought that there was neither white nor black without seeing, nor flavor without tasting. For though in one way they spoke correctly, in another way they spoke incorrectly; for since perception and the perceptible object are spoken of in a twofold way, on the one hand, as potential and, on the other, as active, what they said holds of the latter but not of the former. But they spoke in a simple way about things that are not spoken of in a simple way.

If, then, voice is a sort of consonance, and voice and hearing are in a way one (while in another way not one and the same), and if consonance is a ratio, hearing must also be a sort of ratio. And that is why each sort of excess, whether high or low pitch, also destroys hearing, and similarly excesses in flavor destroy taste, and in colors the intensely bright and dark destroy sight, and in smell the strong odors, whether sweet or bitter, since the perceptual modality is a sort of ratio. That is also why things are pleasant when, being pure and unmixed, they are brought into the ratio—for example, the sharp, sweet, or salty—for they are pleasant then. And in general a mixture is more a consonance than either high or low pitch are, and for touch what can be heated or cooled.[66] The perceptual modality is the ratio, and excessive things pain or destroy it.

Each perceptual modality, then, is of its underlying perceptible subject, is present in the perceptual organ insofar as it is a perceptual organ, and discerns the differences in the underlying perceptual subject—for example, white and black in the case of sight, sweet and bitter in that of taste. And similarly in the case of the others. But since we discern white and sweet and each of the perceptible objects in relation to each, it is by means of something that we also perceive that they are distinct. It is necessary, then, for it to be by perception; for they are perceptible objects. (From this it is clear too that flesh is not the ultimate organ of perception; for then it would be necessary for what discerns to discern by touching it.)

Nor indeed is it possible to discern by separate things that sweet is distinct from white, but both must be clear to some one thing—for otherwise, even if I perceived the one and you the other, it would be clear that they would be distinct from each other. Instead, one thing must state that they are distinct; for sweet is distinct from white. The same thing, therefore, states this; so that, as it states, so too it understands and perceives.

It is clear, then, that it is not possible to discern separate things by separate things—and not at separate times either, as is clear from the following. For just as the same thing states that good and bad are distinct, so also when it states that the one and the other are distinct, the "when" is not coincidental (by "coincidental" I mean, for example, when I say now that that they are distinct, but not that they are distinct now). Instead, it states now that they are that way now—at the same time, therefore. So it is something inseparable [into parts] and discerns in a time that is inseparable [into parts].

But surely it is impossible for the same thing to be moved with contrary movements at the same time, insofar as it is indivisible and in an indivisible time. For if something is sweet, it moves perception or understanding in one way, while what is bitter moves it in a contrary way, and what is white in a distinct way. Is, then, what discerns both indivisible in number and inseparable [into parts], while the being for

66. Reading ἀφῇ δὲ τὸ θερμαντὸν ἢ ψυκτόν. I.e., what is not already at one extreme or the other.

it is separated [into parts]?[67] Surely, it is in one way that what is divisible perceives divided [perceptible] things, but in another way it is this, insofar as it is indivisible, that does so; for the being for it is divisible, but in place and in number it is indivisible.

Or is this not possible? For although what is the same and indivisible admits of contraries potentially, the being for it does not, rather it becomes divided by being activated. And it cannot possibly be white and black at the same time, so that it cannot be affected at the same time by [taking on] the forms of these, if perceiving and understanding are the sorts of things described. On the contrary, it is like what they call a point, in the way that it is one and two, in this way it is [both indivisible] and divisible.[68] Insofar as it is indivisible, what discerns is one and discerns at one and the same time, but in the way in which divisibility belongs to it, it treats the same seal[69] in two ways at the same time. In the way, then, in which it treats the limit[70] as two things, it discerns two separate things, being itself in a way separated; but insofar as it is one, [it treats the limit as] one thing and at one and the same time.

Let the starting-point, then, in virtue of which we say that an animal is capable of perceiving, be determined in this way.

3.3
Imagination

There are two different features by which people most of all define the soul: movement with respect to place, on the one hand, and understanding, discerning, and perceiving, on the other. But both understanding and thinking seem like a sort of perceiving (for in both of these the soul discerns and knows one of the beings). Indeed, the ancients say that thinking and perceiving are the same. Empedocles, for example, said, "Cunning increases in men in relation to what is present to their perceptual modalities" and elsewhere "Hence they always find their thinking too presenting other things,"[71] and the same thing is meant by Homer's "Such is the mind of men";[72] for all of these people take understanding to be corporeal, like perceiving, and both perceiving and thinking to be of like by like, as we determined at the start of our accounts.[73]

427b1 And yet they should have spoken about error too at the same time; for it is something that more properly belongs to animals, and the soul spends more time in this condition. That is why it is necessary either, as some say,[74] that all appearances are

67. *Sens.* 449a5–16, *Somn.* 455a12–27.

true, or that error consists in contact with the unlike; for this is contrary to knowing like by like; but both error and scientific knowledge seem to be the same with respect to contraries. That perceiving and thinking are not the same, then, is evident; for all animals have a share of the former, but few of the latter. Nor is understanding (in which there is what is correct and what is incorrect, where what is correct is wisdom, scientific knowledge, and true belief, and what is incorrect is the contrary of these) the same as perceiving. For the perception of the special perceptibles is always true, and belongs to all animals, while thinking admits also of being false, and belongs to no animal that does not also have reason. Imagination is indeed distinct from both perception and thought, and this itself does not come about without perception, and without it there is no supposition.

But it is also evident that imagination is not the same as supposition. For this affection is up to us [to have] whenever we wish (for it is possible to produce something before our eyes, as is done by those who put things in mnemonic systems and make a mental image of it), but believing is not up to us; for it is necessary that it either be done falsely or done truly. Further, when we believe that something is terrible or frightening, we are immediately affected in the corresponding way, and similarly if it is something reassuring. With imagination, by contrast, our state is just like that of people looking at terrible or reassuring things in pictures. (And of supposition itself there are also different sorts—scientific knowledge, belief, wisdom, and the contraries of these; but the difference between these is for another account.[75])

As regards understanding, since it is distinct from perceiving, and since it seems to be part imagination and part supposition, after having made determinations about the imagination, it is thus necessary to speak about the other. If, then, imagination (*phantasia*) is that in accord with which we say that some appearance (*phantasma*) comes about in us, and if we are not speaking metaphorically, is it some one of these: **428ᵃ1**
a capacity or state in accord with which we discern and grasp truth or falsity? And of this sort are perception, belief, scientific knowledge, and understanding.

That it is not perception is clear from the following. For while perception is either a capacity or an activity, such as sight and seeing, things can appear to us when neither of these is present—for example, the ones in dreams. Next, perception is always present but not imagination. And if they were the same in activity, it would be possible for all beasts to have imagination, but it seems not to be so—for example, in the case of ants, bees, or grubs. Next, perceptions are always true, while most appearances prove false. Next, we do not say, when we are activating [our perceptual modalities] in an exact way regarding a perceptible object, that it [merely] appears to us to be a human, but rather when we do not perceive it clearly, then it may be true or false.[76] And, precisely as we said previously, visible objects appear to us even when we have our eyes closed.

75. *APo*. 1.33, *NE* 6.3, 6.5.
76. Reading τότε ἢ ἀληθὴς ἢ ψευδής.

But then again neither will imagination be any of those things that always prove true—for example, scientific knowledge or understanding; for imagination can also be false.

It remains, then, to see whether it is belief; for there is both true and false belief. But conviction follows upon belief (for it is not possible to believe what we believe without being persuaded of it), and while none of the beasts has conviction, imagination is present in many. Further, every case of belief implies conviction, conviction implies being persuaded, and persuasion implies reason, and while some beasts have imagination, none has reason.

It is evident, therefore, that imagination will be neither belief together with perception, nor belief due to perception, nor a combination of belief and perception,[77] both because of the foregoing considerations and because it is clear that belief is about nothing other than that object, if it exists, which is also the perceptible object. I mean that it is the combination of a belief about the pale and a perception of the pale that constitutes imagination; for imagination is surely not constituted from a belief whose object is the good and a perception of the pale. To be appeared to [in **428b1** imagination], then, is to believe non-coincidentally precisely what one perceives. In fact, though, something can appear falsely, about which one has at the same time a true supposition. For example, the sun appears to be a foot across, although one is persuaded that it is bigger than the inhabited world. It follows [on the view we are considering], then, either that one has jettisoned the true belief one had, even though the thing has remained the same, and one has neither stopped noticing nor been persuaded to change, or else, if one still has the belief, it will be necessary for the same one to be true and false. But it could have become false only if the object changed without one's noticing. Therefore, imagination is not one of these things nor is it constituted from them.

But since, when something is moved a distinct thing can be moved by it, and since imagination seems to be a sort of movement and seems not to occur without perception, but rather to occur in things that perceive and to be of those things that perception is of, and since it is possible for movement to occur as a result of the activity of perception, which movement must be like the perception—this movement could neither be present without perception nor could it belong to non-perceiving things, and it is possible for what has it to do and be affected by many things in accord with it, and for it to be either true or false.

This happens due to the following: Perception of the special perceptibles is true or has the least possible degree of falsity. Second, perception is of the things coinciding with these, and here it is already possible for it to be in error; for about the fact that something is pale, perception cannot be false, but about whether this or something else is the pale thing, it can be false. Third, perception of the common perceptibles that follow along with the coinciding things, I mean, for example, movement and

77. Plato, *Timaeus* 52a, *Sophist* 264a, b.

magnitude, that coincide with the perceptibles. And about these now it is most of all possible to be in error in accord with perception.

But the movement that comes about as a result of the activity of perception, the one that results from these three sorts of perception, will be different. For the first is true as long as the perception is present, while the others may be false whether it is present or absent, and especially when the perceptible object is far away.

If, then, imagination has no characteristics other than the ones that were mentioned, but is what has been described, imagination will be a movement that comes about as a result of the activity of perception. And since sight is perception to the highest degree, imagination (*phantasia*) derives its name from light (*phaos*), because without light it is not possible to see. And because its objects persist and are similar to perceptions, animals do many things in accord with them, some because they lack understanding (for example, beasts) and others because their understanding is sometimes obscured by feelings, diseases, or sleep (for example, human beings).

As regards imagination, then, what it is and why it is, let this much be said.

3.4
Passive Understanding

Concerning the part of the soul by which the soul both knows and thinks, whether this is separable or whether it is not, indeed, separable as a spatial magnitude but only in account, it is necessary to investigate what its different sorts are, and how exactly understanding comes about.

If understanding were like perceiving, it would be either a sort of being affected by the intelligible object or something else of that sort. Therefore, it must be unaffectable but receptive of the form, and potentially such as the form is, although not the same as it, and as what is capable of perceiving is in relation to the perceptible objects, so the understanding must be in relation to the intelligible ones.

Therefore, it must, since it understands all things, be unmixed, as Anaxagoras says,[78] in order that it may master them—that is, in order that it may know them; for something alien intruding into it impedes and obstructs it. So too it has no other nature than this, that it is potentially. Therefore, the [part] of the soul that is called the "understanding" (and I mean by the "understanding" that by which the soul thinks and grasps things) is actively none of the beings before it [actively] understands them. That is why it not reasonable for it to have been mixed with the body; for it would then come to be of a certain sort, either cold or hot, or there would be some instrument for it, just as for what is capable of perceiving; but as things stand there is none. Those who say, then, that the soul is a place of forms speak well, except

78. B12 DK.

that it is not the whole soul, but what is capable of understanding, and it is not actually but potentially the forms.

That the ways in which what is capable of perceiving and what is capable of understanding are unaffectable are not the same is evident from the case of the perceptual organs and the perceptual modality. For the perceptual modality is not capable of perceiving after the perceptible object has been too intense—for example, it cannot perceive sound after hearing very loud sounds, nor see nor smell after very intense colors or odors. But when the understanding understands something intensely intelligible, it [afterward] understands inferior ones not less, but even more; for while what is capable of perceiving does not exist without a body, the understanding is separable. And when the understanding becomes each of the [intelligible] things in the way in which the one who is said to have active scientific knowledge does so (and this comes about when he is capable of activating it by himself), even then it exists potentially in a way, although not in the same way as before learning or discovering [these]—and then it is also capable of understanding itself.

But since magnitude is other than the being for magnitude, and water than the being for water (and so also for many other things, although not for all; for in some cases they are the same), one discerns the being for flesh and flesh [itself] by distinct things or by the same thing in distinct states; for flesh does not exist without matter, but, like the snub, is this in this.[79] It is by means of the perceptual capacity, then, that one discerns the hot and the cold, and those things of which flesh is a certain ratio. But it is by something else—either something separable or the way the state of a bent line is in relation to itself when straightened out—that one discerns the being for flesh. And, again, in the case of abstract beings the straight is like the snub; for it involves extension. But its essence, if the being for straight is distinct from the straight, is something else—let it be, twoness. Therefore, it is by means of a distinct thing that one discerns it, or by means of the same thing in a distinct state. In general, therefore, the way the things are separable from matter is the way it is too with what concerns the understanding.

But someone might raise a puzzle: if the understanding is something simple and unaffectable, and if it has nothing in common with anything, as Anaxagoras says, how will it understand, if to understand is to be affected in some way (for it is insofar as two things have something in common, that the one seems to affect and the other to be affected)? Further, is it itself also intelligible? For either understanding will belong to other things—if it itself is intelligible not in virtue of something else and if the intelligible is something that is one in form—or it will have something mixed with it that makes it intelligible in just the way other things are.

Or rather, [since] "being affected in virtue of something common" has been determined previously,[80] is it that the understanding is in a way the intelligible objects

79. *Met.* 1030b16–18, 1035b27–30, 1036b23–24.
80. 417b2–8.

potentially, although it is none actually before it [actively] understands [them]? It is potentially [these] in the same way as on a wax tablet on which nothing actually written **430ᵃ1**
is present; that is precisely how it is in the case of the understanding. And it is an intelligible object in just the way the intelligible objects are. For in the case of those things that have no matter, what understands and what is understood are the same; for theoretical scientific knowledge and what is scientifically known in that way are the same. (The 5
cause of the understanding's not always [actively] understanding must be investigated later on.[81]) In those that have matter, each of the intelligible objects is present potentially. So in these understanding will not be present (for the understanding is a capacity to be such things without the matter), but being an intelligible object will belong to it.

3.5
Productive Understanding

But since, just as in the whole of nature, there is something that is matter for each kind (and this is what is potentially all those things [that are in the kind]), while there 10
is something else that is causal and productive, because of producing them all (which, for example, is the role of craft in relation to the matter), in the soul too there must be these differences. And one sort of understanding exists by becoming all things, another sort by producing all things, as a sort of state, like light, does; for in a way 15
light too makes the beings that are potentially colors into active colors.

And this [productive] understanding is separable, unaffectable, and unmixed, being in substance an activity; for the producer is always more estimable than the thing affected, and the starting-point than the matter. Active scientific knowledge, for its part, is the same as its object, while potential scientific knowledge is prior in 20
time in the individual, but in general, is not even prior in time; on the contrary, [productive understanding] is not sometimes understanding and at other times not. But, when separated, it is alone precisely that which it is, and it alone is immortal and eternal (but we do not remember because this is unaffectable, while the passive understanding is capable of passing away), and without this nothing understands. 25

3.6
Simple and Complex Intelligible Objects

The active understanding of indivisible things is found in those cases concerning which there is no falsehood,[82] while in those in which there is both falsehood and truth, there is already some sort of composition of intelligible objects as if they were

81. 430ᵃ20–22.
82. *Met.* 1051ᵇ17–1052ᵃ11.

one—as Empedocles said, "as many heads sprouted without necks"[83] and were then combined by love—so too these things that were separate are combined (for example, the incommensurable and the diagonal); and if it is of things that have been or that will be, it understands and combines time in addition. For falsehood always involves composition; for even if [it understands] the pale thing not to be pale, it combines not-pale [with it]. (It is possible to say that all these are also cases of division.) But, at any rate, it is not only false or true that Cleon is pale, but also that he was or will be so. And what produces the one thing is in each case the understanding.

But since what is indivisible is twofold, either potentially so or actively so, nothing prevents someone from grasping what is indivisible when his understanding grasps a length (for this is actively indivisible), nor from doing so in an indivisible time; for the time is divisible and indivisible in a similar way to the length. It is not possible, then, to say what he is understanding in each half of the time; for [the part] does not exist before [the whole] gets divided, except potentially. But if he grasps each of the halves separately, then he also divides the time together with it, and then it is as if they were lengths. But if he grasps the length as composed of both halves, then he does so in the time composed of both halves; things that are indivisible, not with respect to quantity, but in form, he understands in an indivisible time and with an indivisible part of the soul. But coincidentally, and not in the way that those things are, the thing by which he understands and the time in which he understands are divisible, but in the way that those things are, indivisible.[84] For there is also something indivisible in these things, although presumably not separable, which makes the time and the length one. And this is likewise the case for everything that is continuous, both for time and for length.

A point, on the other hand, and every division, and whatever is in this way indivisible, is made clear in the way a privation is. And the same account applies to the other cases (for example, how one knows the bad or the black); for one knows them in a way by their contrary. But what knows must be potentially [the contrary] and in it [the contraries] must be one.[85] And if for something there is no contrary of its causes,[86] it knows itself and is actively and is separable.

A phrase,[87] however, is something [predicated] of something, as too is an affirmation, and each one is either true or false. But understanding is not like that in every case; on the contrary, that of the what-it-is in the sense of the essence is true, and is not something [predicated] of something. However, just as the seeing of a special object is true, but seeing whether the pale is a human or not is not always true, so it is also with [understanding] what is without matter.

3.7
Active and Potential Scientific Knowledge

Active scientific knowledge is the same as its object; but potential scientific knowledge is prior in time in the individual, but in general, is not even prior in time; for all things that come to be do so from what actually is. And it is evident that from the perceptual capacity, which is potentially [perceiving], the perceptible object produces active [perception]; for it is not affected or altered.[88] That is why this is another form of movement; for movement [proper] is the activity of what is incomplete, while an activity in the strict sense—the activity of what is complete—is something else. Perceiving, then, is like mere phrasing and understanding,[89] but when [the perceived object] is pleasant or painful, [the soul], as if affirming or denying, pursues or avoids; and to feel pleasure or pain is to be active with regard to the perceptual mean in relation to what is good or bad, insofar as they are such. Both aversion and desire, when activated, are the same, and the desiring capacity and the aversive capacity are not distinct either from one another or from the perceptual one, although the being for them is distinct. **431a1**

To the thinking soul, however, appearances are like perceptual affections. And when it affirms or denies good or bad, it avoids or pursues. That is why the soul never understands without an appearance.[90] But just as the air made the eye-jelly be such-and-such, and it, in turn, something else, and hearing likewise, the last thing is one, and a single mean, but the being for it is manifold.

What it is by which it determines how sweet and hot differ was stated previously,[91] but one must also say the following. It is indeed one thing, but in the way a defining mark[92] is. And with respect to these, it—being one by analogy and in number—is with respect to each of the two as they are with respect to each other; for what is the difference between puzzling over how it discerns things that are not the same in kind and how it discerns contrary ones—for example, white and black? Let A (white), then, be to B (black) as C is to D, as those are to each other,[93] so that the alternation [A : C :: B : D] also holds. If, then, CD belong to one thing, it will be the case, as for AB too, that they will be one and the same, but the being for them will not be the same, and similarly for the other pair. And the same account would apply if A were the sweet thing and B the white. **431b1**

What is capable of understanding, then, understands the forms in the appearances, and since it is in them that what is to be pursued or avoided is distinguished for it, so, even outside of perception, whenever one is in the presence of appearances, one

92. Or limit (427a13).
93. Reading ὡς ἐκεῖνα πρὸς ἄλληλα.

is moved [to pursuit or avoidance]. For example, perceiving the beacon, because it is fire, one recognizes by the common [perceptual capacity], on seeing it moving, that it is the enemy, but when one calculates by means of the appearances or intelligible objects that are in the soul, just as if seeing them, one then deliberates about future things on the basis of present ones. And when one says there is the pleasant or painful, in that case one pursues or avoids—and so in cases of action generally.

Also, objects that are without reference to action, the true and the false, are in the same kind as the good and the bad; but in the former they differ unconditionally, in the latter relative to a person.

As for objects spoken of in abstraction, one understands them just as one would the snub: insofar as it is snub, not separately; but insofar as it is concave, if someone understood it actively, he would understand it without the flesh, in which the concavity is. That is the way it is with mathematical objects, which are not separable, but which one understands as separable, when one understands them.

But, in general, the active understanding is its objects. Whether or not it is possible for the understanding to understand any separated things when it is itself not separated from a spatial magnitude must be investigated later on.[94]

3.8
Scientific Knowledge, Perception, and Imagination

And now, summing up what has been said about the soul, let us say again that the soul is in a way all the beings; for the beings are either perceptible or intelligible, and scientific knowledge is in a way the scientifically knowable ones and perception the perceptible ones. In what way this is so one must inquire.

Scientific knowledge and perception are divided to correspond to the things, the potential to the potential, the actual to the actual. In the soul, what is capable of perception and what is capable of scientific knowledge are potentially these things, the latter the scientifically knowable ones, the former the perceptible ones. And these must be either the things themselves or their forms. But they are certainly not the **432^a1** things; for in fact it is not the stone that is in the soul, but its form. And so the soul is just like the hand; for in fact the hand is an instrument of instruments,[95] and the understanding is a form of forms, and a perceptual modality a form of perceptible objects.

But since there is no separated thing, it seems, beyond the perceptible magnitudes, it is in the perceptible forms that the intelligible objects are found—both those said in abstraction and those that are states and affections of perceptible things. And that is why, without perceiving, no one could learn or comprehend anything, and

94. This investigation is also mentioned at *Mem*. 450^a7–14, but is not in the extant treatises.
95. Cf. *PA* 687^a20–^{b}7.

when one contemplates, one must at the same time contemplate an appearance;[96] for appearances are like perceptual affections, except that they are without matter.

But imagination is distinct from affirmation and denial; for truth and falsity involve a combination of intelligible objects. But regarding the primary intelligible objects,[97] what difference does their not being appearances make? Or are the others not appearances either, although they are not found without appearances?

3.9
Soul as a Cause of Movement

Since the soul of animals has been defined[98] by two capacities, by the capacity to discern, which is the work of thought and perception, and further by the capacity for causing movement with respect to place, about perception and understanding let the previous determinations suffice—but about what exactly it is in the soul that moves things, one must investigate whether it is some part of the soul, separable either as a spatial magnitude or in account, or whether it is the whole soul, and, if it is some part, whether it is a special one beyond the ones usually spoken about and the ones mentioned, or whether it is one of these.

A puzzle is immediately involved, however, as to what way one should speak of parts of the soul and how many there are. For in a way there appear to be an unlimited number, and not only the ones that some people speak of[99] in distinguishing a rationally calculative part, a spirited part, and an appetitive part, and others,[100] the part that has reason and the non-rational part; for in virtue of the differences because of which they separate these, there will manifestly also be other parts with a greater contrast between them that these, namely, those that have now been spoken about, the nutritive part, which also belongs both to plants and to all animals, and the perceptual part, which could not easily be posited either as non-rational or as having reason. Further, there is the imaginative part,[101] the being for which is distinct from that of all the others, although which of them it is the same as and which it is distinct from involves much puzzlement, if one is to posit separate parts of the soul. And in addition to these there is the desiring part, which would seem to be distinct from all of them both in account and in capacity. And it would surely be absurd to break this up; for in the rationally calculative part there is wish, and in the non-rational part appetite and spirit; and so, if the soul is tripartite, there will be desire in each part.

96. *Sens*. 445b16–17.
97. *Met*. 1037a33–b6.
98. 427a17–19.
99. E.g., Plato, *Republic* 435c–441c.
100. E.g., *NE* 1102a26–32.
101. *Insomn*. 459a15–22.

To come in particular, then, to the point our account has now reached: what is it that moves the animal with respect to place? For movement with respect to growth and withering, which belongs to all, would seem to be caused by what all have, the generative and nutritive part. (Breathing in and out, and sleep and waking, must be investigated later on;[102] for they too involve much puzzlement.) But as regards movement with respect to place, what it is that causes animals to move by progression must be investigated. That it is not the nutritive capacity is clear; for this movement is always for the sake of something and also involves imagination or desire; for nothing that is not desiring or avoiding something is moved, except by force. Further, plants would be capable of movement, and would have some instrumental part for this sort of movement.

Similarly, it is not the perceptual part either; for there are many animals that have perception although they remain stationary and unable to move to the end of their lives.[103] If, then, nature does nothing pointlessly and leaves out none of the necessary things, except in things that are deformed or incomplete, while the animals of this sort are complete and not deformed (a sign of this is that they can generate offspring and have a prime of life and a withering), then they would also have instrumental parts for progression.

Nor is it the understanding part,[104] that is, what is called the understanding, that causes movement; for theoretical understanding does not understand anything doable in action, and says nothing about what is to be avoided and pursued, while the movement in question is always one of avoiding or pursuing something. But even when it does get a theoretical grasp on something of that sort, it does not at once urge pursuit or avoidance, for example, it often thinks of something frightening or pleasant, but it does not urge us to be afraid, although our heart is moved, or, if the thing is pleasant, some other part.

Further, even when the understanding does prescribe and thought tells us to avoid or pursue something, one is not moved, but [sometimes] acts in accord with appetite, like the person who lacks self-control. And, in general, we see that the one who has the craft of medicine does not [ipso facto] give treatment, implying that there is something else that has control of acting in accord with scientific knowledge, but not scientific knowledge. But then again desire does not have control of the movement in question either; for self-controlled people, even when they desire and have an appetite for things, do not do these things for which they have the desire, but instead follow the understanding.

104. Reading τὸ νοητικὸν.

3.10
Understanding, Imagination, and Desire as Causes of Animal Movement

But manifestly these two things do cause movement, either desire or understanding—if one posits imagination as a sort of understanding; for in many cases people follow their imaginations against their scientific knowledge, and in the other animals understanding and rational calculation do not exist, although imagination does.

Therefore, both of these, understanding and desire, are capable of causing movement with respect to place, but understanding that rationally calculates for the sake of something, that is the practical sort, which differs from the theoretical sort with respect to its end. And all desire too is for the sake of something; for the object of desire is the starting-point of practical understanding, and the last thing is the starting-point of the action.[105] So it is reasonable that these two things appear to be the causes of movement: desire and practical thought; for the object of desire moves us, and, because of this, thought causes movement, because its starting-point is the object of desire. Imagination too, when it causes movement, does not cause movement in the absence of desire. There is, then, one thing that causes movement: the desiring part. For if there were two things that caused movement, understanding and desire, they would cause movement in virtue of some common form. But, as things stand, the understanding manifestly does not cause movement without desire (for wish is a desire, and when something is moved in accord with rational calculation, it is moved in accord with wish), and desire causes movement even contrary to rational calculation; for appetite is a sort of desire.

Understanding is in every case correct, while desire and imagination may be either correct or not correct. That is why what causes movement is always the object of desire, which is either the good or the apparent good—not every good, however, but the good that is doable in action. And what is doable in action is what admits of being otherwise.

Manifestly, then, it is a capacity of the soul of this sort—the one called desire—that causes movement. For those, on the other hand, who divide the soul into parts, and divide and separate them in accord with their capacities, the parts turn out to **433b1** be very many—a nutritive part, perceptual part, understanding part, deliberative part, and further, a desiring part; for these differ more from each other than do the appetitive and spirited part.

But since desires come about that are contrary to each other, and this happens when reason and appetites are contraries, and occurs in beings that have a perception of time (for the understanding urges us to resist because of the future, appetite because of the present; for the present pleasure appears both unconditionally pleasant and unconditionally good, because of not seeing the future), what moves us will yet be one

105. *Met.* 1021b29–30, *EE* 1219a11–12.

in form, namely, the desiring part insofar as it is desiring (but the primary [mover] of all is the object of desire; for it moves things without being moved, by being understood or imagined), although in number there will be more than one mover.

Since, then, there are three things, first, the mover, second, that by means of which it moves things, and third, the thing moved, and the mover is twofold, the unmoved one and the one that causes movement and is moved, there is, on the one hand, the one that is unmoved, which is the good that is doable in action, and, on the other, the one that moves and is moved, which is the desiring part (for what is moved is caused to move insofar as it desires, and desire, the active one, is a sort of movement), while the thing moved is the animal.

That by which desire moves is already something bodily—therefore, it is in the works common to body and soul that one must get a theoretical grasp on it. But to speak for now in summary form—what moves in an instrumental way is found where a starting-point and an end are the same, as, for example, in a hinge or ball-and-socket joint, since there the convex and concave are respectively the end and the starting-point [of movement] (that is why the one [the concave socket] remains at rest, while the other [the convex ball] moves), the two being distinct in account, but not separated as spatial magnitudes. For everything is moved by pushing and pulling, which is why, just as in the case of a circle [or sphere], so here too there must be something that remains fixed, and the movement must have it as starting-point.

In general, then, as was said, insofar as an animal is capable of desiring capacity, so far is it capable of moving itself. But it is not capable of desiring without imagination, and all imagination is either rationally calculative or perceptual. It is in the latter, then, that the other animals also have a share.

3.11
Causes of Animal Movement

But one must also investigate what it is that causes movement in the incomplete animals, the ones whose only perceptual modality is touch, and whether it is possible for imagination to belong to them or not, and for appetite too. For pain and pleasure are manifestly present in them, and if these are present, appetite must be too. But how could they have imagination? Or is it that just as they are moved in an indeterminate way, so too these things are present in them—but are present in an indeterminate way?

Perceptual imagination, as was said,[106] also belongs to the other animals, but the deliberative sort exists [only] in the rationally calculative ones (for whether to do this or that is already a work of rational calculation; and it is necessary to measure by one [standard]; for it pursues the greater [good]; and so it must be able to make one appearance from many). And this is the cause of these animals seeming not to have

106. 433b30.

belief, namely, that they do not have the [imagination] that results from a deduction, but this has that.

That is why desire does not have the deliberative capacity, but sometimes conquers and moves wish, while sometimes wish conquers and moves it, like a ball, the desire [doing it to] a desire, whenever lack of self-control occurs. But by nature the higher is more ruling and causes movement, so that there are already three spatial movements caused.[107] But the scientific part is not moved, but remains at rest. And since the one supposition and premise is universal and the other concerns particulars (for the first says that any man of such-and-such a sort should do an action of such-and-such a sort, and the second that this is an action of such-and-such a sort, and I am a man of such-and-such a sort), either it is the latter belief that produces movement, not the universal one, or it is both, but the one remains entirely at rest, while the other does not.

3.12
Interrelations of the Soul's Capacities (1)

The nutritive soul, then, must be possessed by everything that is alive and has a soul, and be possessed from its birth until its death; for what has been born must have growth, a prime of life, and a time of withering away, and these things are impossible without nourishment. Therefore, the nutritive capacity must be present in all things that grow and wither away.

Perception, on the other hand, is not necessarily present in all living things; for those things that have a body that is simple cannot have perception, and nor can those that are not receptive of the forms without the matter. But an animal must have perception, if nature does nothing pointlessly. For all things that are by nature are for the sake of something or will be concomitants of those things that are for the sake of something. Every body that moves by progression, then, if it did not have perception, would perish and fail to arrive at its end, which is the work of nature; for how would it be nourished? For the stationary ones this is indeed present where they have grown. However, it is not possible for a body to have a soul and an understanding that is capable of discerning but not to have perception, if it is not stationary and is generated; for why would it not have this? For either it would have to be better for the soul or for the body. But as things stand it would be so for neither; for the soul would not understand better, and for the body nothing would be better because of that. No body, therefore, that is not stationary has a soul without perception.

But then if it does have perception, the body must be either simple or mixed. But it cannot be simple; for then it will not have touch, but it is necessary for it to have this. This is clear from the following. For since the animal is an animate body, and

107. The one manifesting lack of self-control (appetite overcomes opposing wish); the one manifesting self-control (wish overcomes opposing appetite); and the one manifesting virtue of character (wish and appetite work together in harmony).

every body is tangible, and it is what is perceptible by touch that is tangible, the body of an animal must also be capable of touch, if the animal is to preserve itself. For the other perceptual modalities perceive through other things: smell, sight, and hearing. But if, when touching things, an animal does not have perception of them, it will be unable to avoid some of them and take others. And if that is so, it will be impossible for the animal to preserve itself.

That is why taste too is like a sort of touch; for it is concerned with nourishment, and nourishment is a tangible body. Sound, color, and odor, on the other hand, do not nourish, nor do they produce growth or withering. So it is necessary for taste too to be a sort of touch, because it is a perception of what is tangible and nourishing. These perceptual modalities, then, are necessary to the animal, and it is evident that it is not possible for an animal to exist without touch.

The others are for the sake of the good and it is not just to any random kind of animal but in some (for example, the kind that moves by progression) that their presence is necessary; for if an animal that moves by progression is going to preserve itself, it must perceive not only by touching but also from a distance. And this would be the case if it had the capacity to perceive through a medium, the latter being affected and moved by the perceptible object, and the animal by the medium. For just as when what moves something with respect to place makes it change to a certain extent, and what has pushed something else makes the latter push as well, the movement occurs through an intermediate, and just as the first moves and pushes without being pushed, and only the last is pushed and does not push, while the intermediate is both (and the intermediates are many), so it is too in the case of alteration, except that things are altered while remaining in the same place. For example, if someone presses into wax, the wax is moved to the extent that he presses, while stone is not moved at all, and water is moved to a further extent. Air, however, is moved to the greatest extent, and acts and is acted upon, if it remains in place as one thing.

That is why in the case of reflection too, it is better to say not that sight issuing [from the eye] is reflected back,[108] but that the air—to the extent that is one thing—is affected by shape and color. But over a smooth surface it is one thing, which is why it in turn moves sight, just as if the seal [pressed] into the wax were to pass on to the extent of reaching the limit.[109]

3.13
Interrelations of the Soul's Capacities (2)

It is evident that the body of an animal cannot be simple—I mean, for example, composed of fire or of air. For without touch it cannot have any other perceptual modality; for every animate body is capable of touch, as was said.[110] All the

108. Plato, *Timaeus* 45b–46c.
109. 427a13–14.
110. 434b11–19.

other elements, except earth, could come to be perceptual organs, but they all produce perception through something else, that is, through media, while touch involves touching things, which is why indeed it has this name. And yet even the other perceptual organs perceive by touch, but through something else, while touch alone seems to do so through itself. So none of these other elements could compose the body of an animal. Nor, then, can it be composed of [just] earth. For touch is, as it were, a mean between all tangible objects, and its perceptual organ is receptive not only of the differences in earth,[111] but also of hot and cold and all the other tangibles. And that is why we do not perceive with our bones, hair, or other such parts: because they are composed of earth. It is also because of this that plants have no perceptual modality at all, because they are composed of earth. But without touch no other perceptual modality can be present, and its perceptual organ is composed neither of earth nor of any of the other elements.

It is evident, therefore, that this is the only perceptual modality lacking which an animal must die; for it is not possible for anything to have this if it is not an animal, nor is there any besides it that something must have to be an animal. And that is why the other perceptible objects (for example, color, sound, and odor) do not in excess destroy the animal but only the perceptual organs—except coincidentally, such as when at the same time as the sound a push or a blow takes place); and by visible objects or an odor other things are caused to move which destroy by touch. And flavor too destroys only insofar as it is at the same time capable of touch. But excess in tangible objects—for example, hot ones, cold ones, or hard ones—does away with the animal; for excess in every perceptible object does away with the perceptual organ, so that in the case of tangible objects it does so to touch, which is what life is defined by; for it has been proved[112] that without touch it is impossible for an animal to exist. That is why excess in tangible objects destroys not only the perceptual organ but also the animal, because this is the only one that it must have.

The other perceptual modalities, as was said,[113] the animal has not for the sake of being but for the sake of well-being. For example, it has sight in order to see, since it lives in air or water, or, in general, in what is transparent; taste because of what is pleasant and painful, in order that it may perceive these in nourishment, have appetite, and be moved; hearing so that something may be signified to it; and a tongue so that it may signify something to another.

DE SENSU ET SENSIBILIBUS*

On Perception and Perceptible Objects

1
Introduction

Since we have drawn our distinctions about the soul by itself, and about each of its capacities in turn, we must next make our investigation of animals and of all things that have life, as to which of their actions are special to some and which are common to all of them. What has been said about the soul, then, is to be assumed throughout, but let us speak about what remains, starting with what comes first. **436ª1** 5

It is evident that the most important [affections], both those that are common and those that are special to certain animals, are common to body and soul: perception, memory, spirit, appetite, and, in general, desire, and in addition to these, pleasure and pain. For these belong to pretty much all animals. 10

In addition, some [affections] are common to all things that partake of life, while others pertain only to some animals. The most important of them happen to be four pairs: wakefulness and sleep, youth and old age, inhaling and exhaling, and life and death. We will investigate them and determine what each of them is and due to what causes it occurs. 15

It is for the natural scientist also to consider the primary starting-points of health and disease; for neither health nor disease can occur in things deprived of life. That is why among pretty much most of the natural scientists and those among the doctors who pursue their craft in a more philosophical manner, the former end up discussing matters pertaining to the craft of medicine, while the latter begin their medical craft starting from matters pertaining to natural science.[1] 20 **436ᵇ1**

That all the [affections] mentioned are common to body and soul is not unclear. For they all take place either together with perception, or through perception; and some happen to be affections of perception, others states of perception; some of them protect and preserve it, while still others are destructions or privations of it. And that perception comes to the soul through the body is clear both with and without argument. 5

About perception and perceiving, however, what it is and due to what causes this affection takes place in the animals was spoken about previously in the *De Anima*. It is necessary that perception belongs to animals insofar as each one is an animal; for it is by this that we distinguish between being an animal and not being an animal. But, now, as for each particular perceptual modality, touch and taste necessarily go along 10

* Translated by Klaus Corcilius. Text: J. Winzenrieth, *Les* Parva Naturalia *d'Aristote: Édition et Interprétation* (PhD diss., Sorbonne, Paris & LMU Munich, 2023).

1. *Juv*. 480ᵇ22–30.

with all animals, touch due to the cause stated in the *De Anima*,[2] and taste because of nourishment; for it distinguishes the pleasant and the unpleasant in nourishment, so as to avoid the one and pursue the other, and flavor is, in general, an affection of what is nutritive.

The perceptual modalities that perceive through external media belong to animals that move by progression, that is, smell, hearing, and sight. They all belong to the animals that possess them for the sake of preservation, in order to pursue and perceive their nourishment beforehand and to avoid what is bad and destructive for them. But **437ᵃ1** to animals that also possess practical wisdom they belong for the sake of the good; for they report many differences, from which practical wisdom concerning intelligible objects and things doable in action comes about.

Of these latter perceptual modalities sight is superior with respect to what is necessary [for survival] and also intrinsically, but with respect to understanding and coincidentally it is hearing. For the capacity of sight reports many differences of all sorts, because all bodies partake of color, so that the common perceptibles too are most of all perceived through sight (by "common ones" I mean magnitude, shape, movement, number). Hearing reports only the differences of sounds, and to few animals also the differences of voice. But coincidentally hearing contributes the greatest share to practical wisdom. For speech, since it is audible, is a cause of learning, not intrinsically but coincidentally; for it consists of names and each name is a symbol. That is why among those deprived from birth of either of the two perceptual modalities, the blind tend to be more practically wise than the deaf and mute.

2
Composition of the Perceptual Organs: The Eye

About the capacity that each of the perceptual modalities possesses we have spoken previously;[3] about the body in whose perceptual organs they naturally come to reside, however, some [thinkers] inquire by distributing them among the elements of bodies. But since they are at a loss as to how to match four [elements] with five [perceptual modalities], they struggle about the fifth.

They all ascribe sight to fire because they are ignorant of the cause of a certain affection; for when the eye is pressed and moved it appears that fire flashes out from it. And this naturally occurs when it is dark, or else when the eyelids are closed; for then too there is darkness. But this also involves another puzzle. For if it is not possible for it to escape the notice of someone who is perceiving and seeing that he is seeing something, it is immediately necessary that the eye sees itself. Why, then, does this not occur when the eye is at rest?

2. 2.5–12.
3. *DA* 2.7–11.

The causes of this, and also of the puzzle connected to the belief that sight is fire, must be grasped from the following. Smooth things naturally shine in the dark, although certainly without producing light, and the so-called black and middle of the eye is smooth. And this [flashing out of fire] appears when the eye is [pressed and] moved because what happens is just as if the one thing became two. This is the effect of the speed of the movement, so that what sees and what is seen seem to be different. That is also why this does not happen unless [the eye is moved] swiftly and in darkness; for what is smooth naturally shines in the dark (for example, the heads of certain fishes and the ink of the cuttlefish), and so when the eye changes slowly what sees and what is seen do not seem to be one and two at the same time as a result. And in that way, the eye sees itself just as it does in a reflection.

For if sight really was fire, as Empedocles says[4] and is written in the *Timaeus*,[5] and seeing did take place by the emission of light, as if from a lantern, why would the eye not also see in the dark? To claim that it is extinguished when issuing out [from the eye] in darkness, as the *Timaeus* says, is completely empty. For what is extinction of light supposed to be? For it is by something wet or cold that the hot and dry is extinguished, as seems to be the case with fire and the flame in coal-like things, but it is evident that neither of these things holds true of light. If, however, it[6] is present [in light] but it escapes our notice because of its feebleness, then light, by day and during rain, would have to be extinguished, and it would have to get darker during frost; at any rate, flame and bodies on fire undergo some such affection. But none of this occurs in the case at hand.

Empedocles seems at times to think that we see when the light is emitting [from our eyes], as has been said before. At any rate, he says this:

> As when a man planning a journey had armed his lamp
> —the gleam of a fire blazing through the stormy night—
> by adjusting sides thereto, protections against winds of all kinds,
> which scatter the breath of the blowing winds,
> but the fire that was leaping outward according to its expansion,
> [where] they were perforated straight ahead with wonderful [passages],
> was shining down upon his doorstep with incessant beams—
> So at that time the primeval fire, enclosed in the membranes,
> spread through the ring-shaped iris by means of fine pores,
> which, while fending off the depth of the water flowing around,
> let the fire pass outward according to its expansion.[7]

4. 437ᵇ23–438ª3.
5. 45b–d, 67e–68b.
6. I.e., the hot and the dry.
7. B84 DK. Trans. Primavesi.

Sometimes, then, this is how he says that we see, but at other times he says that we see by means of the effluences from the objects seen.

Democritus, when claiming that the eye is water, speaks correctly, but he does not speak correctly in thinking that seeing is mirroring; for this occurs because the eye is smooth, and it is not in it but in the one who is seeing. For this affection is reflection, but it seems that there was not yet anything clear to him in universal terms concerning mirroring and reflection. But it is strange too that it did not occur to him to be puzzled about why it is only the eye that sees, but none of the other things in which mirror images appear.

It is true, then, that the eye consists of water. However, seeing does not take place insofar as it is water but insofar as it is transparent, which is common also to air. But water is easier to confine and compress than air. That is why the eye-jelly and the eye consist of water. This is also clear from the facts themselves. For when the eyes are destroyed it is evident that what flows out is water, and at least in very young fetuses, the eye-jelly is excessively cold and bright; and in blooded animals the white of the eye is fatty and oily, in order that its liquid may remain unfrozen. That is why the eye is the part of the body that is most insensitive to cold; for no one has ever felt cold under the eyelids. The eyes of non-blooded animals have a hard skin [instead of eyelids] and this is what provides them with shelter.

It is wholly absurd, though, for the eye to see because of the emission of something that either extends as far as the stars or grows together [with rays that proceed from the object] once it goes out a certain distance, as some say.[8] For it would be better [to say that] it grows together where the eye begins. But this is naive too; for what does it mean to say that light grows together with light? Or how is it possible for this to happen? For it is not any random thing that grows together with any other random
438b1 thing. And how can the internal light grow together with the external light? For the membrane [of the eye] is in between them.

We have spoken elsewhere[9] about the fact that one cannot see without light. But whether it is light or air that lies between the object seen and the eye, it is the movement that goes through this that produces the seeing.[10] And it is reasonable that the inner part of the eye consists of water; for water is transparent. And just as seeing on the outside is not possible without light, so also on the inside. Therefore, it must be transparent. Therefore, it is necessary for it to be water, given that it is not air. For the soul, or better, the perceptual part of the soul, is not located on the eye's surface, but clearly inside. That is precisely why it is necessary for the inner part of the eye to be transparent and receptive of light. And this is also clear from what happens. For to some who were struck in battle by a blow on their temple so that the eye ducts[11] were severed, it seemed that darkness was falling, as if a lamp had been put out, because

8. Plato, *Timaeus* 45c.
9. *DA* 418a27–b3.
10. *GA* 780a3–4, 781a3–12.
11. *HA* 495a11–18, *PA* 656b16–18.

the transparent part, the so-called eye-jelly, which is like a sort of lantern screen, had been severed.

So, if these things happen in the way we say they do, it is clear that if one must in this way assign and attach each of the perceptual organs to one of the elements, one must suppose that the part of the eye that is capable of seeing is composed of water, that what is capable of perceiving sounds is composed of air, and that that of smell is composed of fire—for what smelling is actively, that is what the part that is capable of smelling is potentially. For the perceptible object makes the perceptual modality active, so that it is necessary for it to be potentially the object previously. An odor is a sort of smoky exhalation, and smoky exhalations originate from fire. That is also why the perceptual organ special to smell has its place in the brain. For the matter of what is cold is potentially hot. And the process of generation of the eye takes place in the same way. For its constitution originates from the brain; for it is the wettest and coldest of the parts in the body. What is capable of touch is composed of earth, and the capacity of taste is a certain form of touch. And because of this the perceptual organ of both taste and touch is located near the heart; for it is set over against the brain and it is the hottest of the parts.

And as regards the perceptual parts of the body, then, let the distinctions be made in this way.

3
Sight and Color

About the perceptible objects corresponding to each of the perceptual organs—I mean color, sound, smell, flavor, and touch—we have spoken in universal terms in the *De Anima*,[12] as to what their work is, that is, what as regards each of the perceptual organs its activity is. But what exactly one should say about what each single one of them is—for example, what color, sound, smell, or flavor is, and similarly also about touch, must be investigated, and first about color.

Each, then, is said of things in two ways: in activity or in potentiality. In which way, then, active color and sound are the same as, or different from, the active perceptions—that is, seeing and hearing—has been stated in the *De Anima*.[13] But let us now say what each of them must be in order to produce the active perception.

As has been said in that investigation[14] about light, that it is coincidentally the color of the transparent—for whenever something fiery is in something transparent, its presence is light, and its privation is darkness. And what we call "transparent" is not special to air, water, or any other of the bodies called "transparent," but is a common nature and capacity, which is not separable, but in them, and is also present

12. 2.7–11.
13. 425^{b}26–28, 426^{a}10–12.
14. *DA* 418^{a}11–12.

in other bodies, in some more and in some less. Just as, then, it is also necessary for there to be some extremity of the bodies, so too of this nature. The nature of light, then, is present in the transparent as in something indeterminate. But it is clear that the extremity of the transparent present in bodies must be something, and that this is color will be apparent from the facts. For in that case color is in the limit insofar as it is a limit (that is also why the Pythagoreans used to call the surface "color"); for it is in the limit of the body, but is not the body's limit; rather, one must regard precisely the same nature that is colored outside as also colored inside.

439ᵇ1 Both air and water appear colored; for their gleam is also of this quality. But in the former case, because their color is in something indeterminate, neither the air nor the sea have the same color for those who approach them from nearby or at a distance. In bodies, by contrast, unless the environment makes them change, the appearance of their color is determinate as well. It is clear, therefore, that it is the same thing that is capable of receiving color in the one case as in the other. Therefore, inasmuch as it is present in the bodies (and it is more or less present in all of them), the transparent makes them partake of color.

But since color is in the limit, it would be a sort of limit [of the transparent]. So color would be the limit of the transparent in a determinate body. And regarding the transparent bodies themselves—for example, of water and of anything else of this sort—in all of them that appear to have a color of their own, it is present at the extremity of all of them in the same way.

Precisely the same thing, then, that produces light in the air can also be present in the transparent, and it can also not be present, but lacking. So just as in the air one of them is light and the other darkness, so white and black come to be present in bodies.

But it is necessary now to speak about the other colors by determining in how many ways they can come about. For it is possible that they come about in the following way, namely, that the white and the black are so juxtaposed that each of them is invisible on account of its smallness while their combination is visible. For this combination cannot appear either white or black. But since it is necessary that it have some color, and neither of these two is possible, it is necessary that it be something mixed and another form of color. In this way, then, it is possible to suppose that there is a plurality of colors besides white and black, and that the plurality is due to the ratio. For it is possible for them to be juxtaposed in a ratio of three to two, or three to four, or in accord with other numbers; others, however, may in general be juxtaposed in accord with no ratio, but in accord with some excess and deficiency that is incommensurable. And they will certainly behave in the same way as concordant sounds. For the colors that are [mixed] in the simplest numerical ratios, just like the concordant ones there (and these seem to be the most pleasing of the colors, like **440ª1** purple and red, but there are few of this sort, and for the same reason that explains why there are few concords too); and those that are not [mixed] in numerical ratios are the other colors. Or may it also be that all colors are [mixed] in numerical ratios,

those that are ordered at least, while those that are not, as well as the previous ones when they are not pure, are such because they are not [mixed] in numerical ratios?

This, then, is one mode of generation for the colors. Another is for them to appear through each other, as painters sometimes produce them, when they paint one color over another more manifest color, as, for example, when they wish to make something appear to be in water or in air, and as the sun by itself appears white, but red [when viewed] through mist and smoke. There will be many colors also in the same way as the one mentioned earlier; for there should be some ratio of the colors at the surface to those underneath, while others may not stand in any ratio at all.

To say, then, as the ancients did, that color is an effluence and that it is seen due a cause of this sort is absurd. For it is necessary for them then to make perception be in every case due to contact, so that it is better to say from the outset that perception occurs due to the medium of perception being moved by the perceptible object than [to invoke] contact and effluences.

In the case of juxtaposed colors, it is necessary to accept that there is an invisible magnitude, just as it is necessary to accept that there is an imperceptible time, in order that the incoming movements may escape our notice and appear to be one [color] because of their simultaneous appearance. But here[15] there is no such necessity. On the contrary, when the color at the surface is unmoved as when it is moved by the underlying color, it will not produce the same movement. That is why in fact it appears to be another color and neither white nor black. Therefore, if there cannot be any invisible magnitude, but everything is visible from some given distance, then this very juxtaposition [of colors] will be a sort of mixture of colors. And in this other way [of generating colors by superposition] nothing prevents a sort of ordinary color from appearing to those who view it from afar. That there is indeed no invisible magnitude must be investigated later on.[16]

But whether there can be a mixture of bodies, not only in the way which some believe to be the only one (namely, by a juxtaposing of their smallest parts that is not evident to us through perception), but wholly and completely in every way, just as has been stated in universal terms as regards all bodies in the investigation of mixture,[17] [cannot be discussed here, but has to be presupposed]. For in that other way those things alone admit of being mixed that can be divided into smallest parts, like human beings, horses, or seeds. For of human beings, a human being is the smallest part, and of horses, a horse, so that it is by means of their juxtaposition that the joint mass of both is "mixed." But we do not say that one human being can be mixed with one horse. For all the things, however, that do not divide into smallest parts, it is not possible that a mixture of them comes about in that way, but only by means of all of them being mixed completely; and these very things are by nature most apt for

15. I.e., in the case of the superimposed colors.
16. 445^{b}20–29, 446^{a}16–20.
17. *GC* 1.10.

mixture. How it is possible that this [complete] mixture comes about has been stated previously in the investigations concerning mixture.[18]

At the same time, in what way it is necessary that when things are mixed their colors are mixed too, is clear, and also that this is the principal cause of why there are many colors, and not superposition or juxtaposition. For it is not the case that the mixed ingredients result in the appearance of one color if viewed from far away and not so if viewed from close, but rather from everywhere. And there will be many colors because it is possible to mix the ingredients with each other in accord with many ratios, either in numerical ratios or in accord with excess only.

And the other things we have said about the juxtaposed or the superimposed colors can also be applied in the same way to those involving mixture. Due to what cause the forms of colors are determinate and not unlimited in number, and also those of taste and of sounds, must be investigated later on.[19]

4
Flavor

What color is and due to which cause there are many colors has been stated, then, and about sound and voice we have spoken previously in the *De Anima*.[20] Now we must speak of smell and flavor. For they are pretty much the same affection, but they are not each present in the same [things]. The flavor kind is clearer to us than the **441ª1** smell kind. The cause of this is that smell is the worst even among our own perceptual modalities, while touch is the most exact, in comparison to all the other animals, and taste is a sort of touch.

The nature of water tends to be flavorless. And it is necessary either that the water will have the kinds of flavors in itself but they will be imperceptible on account of [their] smallness, as Empedocles claims;[21] or else that water is a certain sort of matter, like a universal seedbed[22] of flavors, and that while all flavors come from water, each single one of them comes from a distinct part of it; or that water possesses no internal differentiation [in terms of flavors] and that what acts on it is the cause [of the flavors]—for example, if one were to say that heat and the sun [are such causes].

Among these three views, the falsity of the way Empedocles speaks is exceedingly easy to detect. For we see that the flavors of fruits change due to the heat when they are picked to be exposed in the sun and roasted. This implies that they do not come about due to drawing something from the water but due to changes that occur in the fruit itself. And when they are dried and are left lying for some time, they change

18. *GC* 1.10.
19. 445^b20–29, 446^a16–20.
20. 2.8–9.
21. B102 DK.
22. Cf. *Ph.* 203^a21–22.

from sweet to harsh and bitter, and acquire all sorts of flavors. And when they are boiled, they change into (one might almost say) all kinds of flavors.

Similarly, it is also impossible for water to be the matter of a universal seedbed [of flavors]; for we see that from the same water as nourishment[23] distinct flavors are produced.

The remaining option, then, is that the water changes by means of a certain affection. It is clear, therefore, that water does not acquire this capacity, which we call "flavor," due to the capacity of the heat alone. For water is the finest-grained of all liquids, even finer-grained than oil itself (though oil extends over a broader area than water on account of its viscosity). Water, by contrast, is non-viscous, which is also why it is more difficult to keep water in one's hand than oil. And since it is evident that water by itself alone does not become coarse-grained when heated, it is clear that the cause [of the flavor] must be something else; for all the flavors exhibit a greater degree of coarse-grainedness [than water].[24] Heat is [just] a co-cause.

All the flavors that are present in the fruits also appear to occur in earth. That is why many of the ancient natural scientists say that water is like the earth through which it travels. And this is especially clear in the case of saltwater; for salt is a form of earth. Also, when waters are filtered through ash, which is bitter, it makes the flavor bitter. And there are many springs that are bitter, or sharp, or have all sorts of other flavors.

It is reasonable that the flavor kind occurs the most in plants. For the wet, just like everything else, is naturally affected by its contrary. And the contrary of the wet is the dry. That is why [water] is somehow affected by fire; for the nature of fire is dry, but heat is a special affection of fire, and the dry a special affection of earth, as was said in the investigations concerning the elements.[25] Insofar as it is fire, then, or insofar as it is earth, it will not affect or be affected in any way, and neither will any other body, but rather insofar as there is a contrariety present in each of them, to that extent all things both affect and are affected.

In just the way, then, in which those who steep colors or flavors in liquid make the water have that same quality, in that same way nature too [steeps] the dry and the earthen [in liquid], and by filtering the liquid through the dry and earthen and causing it to move by means of heat, it makes it acquire a certain quality. And this is flavor, the affection in the wet produced by the dry just mentioned that is capable of altering [the perceptual modality of] taste from potentiality to activity. For it brings the perceptual part into that state, which was previously in one of potentiality. For perceiving does not correspond to learning but to contemplating.

That the flavors are not an affection or a privation of everything dry but only of what is nourishing, one must grasp from the following. Neither the dry without

23. I.e., for fruits and the like.
24. Since they are sorts of humors or "juices."
25. *GC* 2.2–3.

the wet nor the wet without the dry [has flavor]; for one [of them] by itself is no nourishment for animals and moreover also not for plants, but only the mixture. And of the nourishment received by animals it is the tangible among the perceptible [bodies] that produce growth and withering. For it is the cause of these things insofar as what is received is hot or cold (for it is these that produce growth and withering), but it nourishes insofar as what is received is tasteable (for all are nourished by what is sweet, either simply so or mixed).

One must make determinations concerning these things in the investigations concerning generation,[26] now, however, we touch upon them only as far as is necessary. For the hot causes growth, crafts the nourishment, by means of drawing upward what is light, and leaving behind what is salty and bitter due to their heaviness.

And, indeed, what the external heat does in external bodies, this is what the [internal heat] in the nature of animals and plants [does], which is why they are nourished by the sweet. Other flavors are mixed into the nourishment in the same way as the salty and sharp take the place of seasoning, because of these counterbalancing the excessive nourishing effect of the sweet and its tendency to remain on the surface [of the stomach].

In the same way in which the colors are mixtures of white and black, so the flavors are of sweet and bitter, and are so, then, in accord with a ratio of the more and the less, either in accord with certain numbers belonging to the mixture or movement,[27] or else in an indeterminate way. Those flavors, however, that when mixed produce pleasure occur only in numerical proportions. The flavor of the sweet is the oily, and the salty and the bitter are pretty much the same, and the pungent, harsh, astringent, and sharp are in between. For the forms of flavors are pretty much equal in number to those of the colors. For there are seven forms of each of them, provided one takes, as is reasonable, the gray to be some sort of black. It remains, in fact, that yellow pertains to white just as the oily pertains to the sweet, and that red, purple, green, and blue are between white and black, and the other colors mixed from them. And just as black is a privation of the white in the transparent, so the salty and the bitter are privations of the sweet in the nourishing liquid. That is also why the ash of everything that has been burned up is bitter; for what is drinkable has been extracted from it.

Democritus and most of the natural scientists who speak about perception do something that is extremely absurd. For they make all perceptible objects tangible ones. And yet, if this is how things are, it is clear that each of the other perceptual modalities will be a sort of touch. But it is not difficult to see that this is impossible. Further, they all treat objects that are common to all perceptual modalities as special perceptibles. For magnitude and shape, the rough and the smooth, and also the sharp and the dull in solid objects, are common to the perceptual modalities, and if not common to all, they are at least common to sight and touch. That is also why

26. *GA* 762ᵃ12–13, 776ᵃ28–30.
27. 440ᵃ20–31.

the perceptual modalities can be mistaken about the common perceptibles, but not mistaken about the special ones—for example, sight about color and hearing about sounds.

Others reduce the special perceptibles to the common ones, as Democritus does;[28] for he says that the white and the black are one rough and the other smooth, and he reduces the flavors to the shapes [of atoms]. And yet, to recognize the common ones either belongs to no [particular] perceptual modality or else it belongs more to sight.[29] But if it belongs more to taste, then since it belongs to the most exact perceptual modality to discern among the smallest items in each kind, it follows that taste would also have to perceive the other common perceptibles best and be most apt for discerning the shapes.

Further, all perceptible objects involve contrariety—for example, in color, the white is contrary to the black and in flavors the bitter is contrary to the sweet. But it does not seem to be the case that shape is contrary to shape; for which of the polygons is contrary to the circle? Further, since shapes are unlimited in number, it is necessary that the flavors be unlimited in number as well; for why would one [flavor produced by a given shape] produce perception and another not?

The tasteable and flavor have now been spoken about. For the investigation of the other affections of the flavors properly belong to the natural inquiry concerning the plants.[30]

5
Smell and Odor

It is in the same way that one should also understand the case of odor. For what the dry produces in liquid[31] is precisely what the flavored and wet produces in another kind, in air and water alike. And even though we predicated "transparent" of them in common just now,[32] it is not insofar as it is transparent that the smellable is such, but insofar as it is capable of washing and cleansing what is flavored and dry. For the smellable is not only present in air but also in water. This is clear in the cases of the fishes and the hard-shelled animals. For they are observed to smell even though there is neither air in the water (for air floats to the surface when it occurs in the water) nor do they breathe. If, then, one were to assume that air and water are both wet, it would follow that odor would be the nature of what is flavored and dry present in what is wet, and that the smellable would be this sort of thing.

28. A135 DK.
29. 437ᵃ5–9.
30. Not extant.
31. 441ᵇ15–23.
32. 438ᵃ14–15.

That the affection comes from something flavored is clear from a consideration of the things that have an odor and those that do not. For the elements—fire, water, air, earth—are odorless, because both the dry and the wet among them are flavorless, unless one produces a mixture of them. And that is why the sea has an odor—for it has flavor and dryness—and why salt is more odorous than soda[33] (as the oil it exudes shows), while soda is more earthen. Further, stone is odorless, for it has no flavor. Woods, by contrast, are odorous, for they have flavor; but among these, the watery ones are less so. Further, in the case of metals, gold is odorless, for it has no flavor, while bronze and iron are odorous. But when the liquid is burned away, the dross of all of them becomes more odorless. Also silver and tin are more odorous than some and less so than other [metals]; for they are watery.

Some believe that the smoky exhalation is odor, since it is common to earth and air, and everyone is inclined to say this about odor. That is also why Heraclitus spoke in this way, saying that if all the beings were to become smoke, noses would distinguish them.[34] But everyone is inclined to say this about odor, some saying it is vapor, others that it is an exhalation, and still others that it is both of these. But vapor is some sort of the wet, and the smoky exhalation, as was said,[35] is common to air and earth, and water is formed from vapor, and a certain form of earth is formed from the smoky exhalation. But [odor] does not seem to be either of them. For vapor consists of water, and it is impossible for the smoky exhalation to occur in water. But the animals in the water also smell, as was said previously.[36] Further, exhalation is invoked in
443b1 a similar way to the effluences;[37] if the latter is not correct, then neither is the former.

That it is possible to enjoy the wet, both in the breath and in the water, and to be somehow affected by what is flavored and dry, is not unclear. For air too is in its nature wet. Also, if indeed what is [flavored and] dry produces an effect like being washed out in liquids and in the air, it is evident that smells must be analogous to flavors. But surely this *is* what happens in some cases. For there are pungent and sweet smells, and also harsh, astringent, and oily smells, and one may say that rotten smells are analogous to bitter flavors, which is why just as bitter things are hard to swallow, rotten ones are hard to inhale. It is clear, therefore, that the precise thing that is flavor in water is odor in air and water. And that is why cold and solidification dull flavors and make smells disappear; for cooling and solidification make the heat, which is the mover and producer [of these affections], disappear.

There are two forms of the smellable; for it is not the case, as some claim,[38] that there are no forms of the smellable, because there are. But one must distinguish in which way there are and in which way there are not.

33. Sodium carbonate.
34. B7 DK.
35. 443a21–22.
36. 443a3–6.
37. 440a15–20, 442a29–b23.
38. Plato, *Timaeus* 66 D.

One form of the smellable is ordered in accord with the flavors, as we have said,[39] and they are pleasant and painful coincidentally. For because they are affections of what is nourishing, to those that have an appetitive for it, its odors are pleasant, but they are not pleasant to those that are full or not in need of anything, and they are also not pleasant to any of those to whom the nourishment that has these odors is not pleasant either. Therefore, these smells, as we have said, are coincidentally pleasant and painful, which is also why they are common to all animals. The other odors, by contrast, are intrinsically pleasant—for example, those of flowers. For they neither provide any invitation, either more or less, in relation to nourishment, nor do they contribute anything in relation to appetite, but rather the contrary. For what Strattis said when mocking Euripides is true: "when you boil lentils don't pour in perfume."[40] And those who nowadays mix such potent ingredients into drinks force the pleasure by habituation, until something pleasant arises from two perceptions as if it were from one.

This form of the smellable is special to human beings, whereas the one that is ordered in accord with the flavors belongs also to the other animals, as was said previously.[41] And the forms of those odors, because they are pleasant coincidentally, are divided in accord with the flavors, but this form is no longer [divided in this way], because its nature is intrinsically pleasant or painful. The cause of this sort of smell being special to human beings is because of the cooling in the region around the brain. For since the brain is by nature cold, and the blood in the small blood vessels around it is fine-grained and pure, but easily cooled (which is also why the exhalation from the nourishment when cooled by this place causes diseased discharges), this form of smell serves human beings as an aid for health; for it has no other work. And it manifestly does it; for nourishment, both dry and wet, since it is pleasant, is often unhealthy, but the aid resulting from the smell of an object that has an intrinsically pleasant smell is (one might almost say) always beneficial whatever condition they happen to be in. And that is why it occurs through respiration, not in all animals, but in human beings and among blooded animals in the four-footed ones and in all those that share more in the nature of air. For since the odors rise toward the brain, due to the lightness of their heat, the parts of the body around that place are in a healthier condition. For the capacity of smell is hot in nature. But nature has made use of breathing for two things: for the work of aiding the chest and for the secondary work of smelling;[42] for during breathing it produces a movement through the nostrils as if from a side entrance. And this form of odor is special to the nature of the human being because he has the largest and also the wettest brain for his size in comparison with the other animals. In fact, it is because of this that (one might almost say) only the human being that perceives and enjoys the odors of flowers and other such

42. *Juv*. 473^{a}19–25.

things. For the heat and movement of these odors is commensurable with the excess
444ᵇ1 of the wetness and coldness in this place. To all those animals that have lungs, due to the fact that they breathe, nature has given the capacity to perceive the first kind of odor, so as not having to produce two perceptual organs. For, since they too breathe
5 in this way, just as in human beings it is enough for the perception of both [forms] of smellable things, in these animals it is enough for the perception of the first only.

That the non-breathing animals have a perception of the smellable is evident. For fishes and the entire insect kind all perceive it exactly even from a distance, due to the
10 nourishment-related form of smell, even when far away from their proper nourishment, like the bees do with their honey and the kind of small ants, which some call *knipes*.[43] And among the marine animals, the purpuras and many other animals of this sort are capable of sharply perceiving their nourishment due to its odor.

15 What they perceive it with, however, is not equally evident. That is why one might be puzzled as to the means by which they perceive smell, if indeed in breathing animals smelling comes about in only one way (for this appears to be the case in all breathing animals), but none of these animals breathes, although they do perceive [odor]—unless there is another perceptual modality beyond the five. But this
20 is impossible. For smelling is of the smellable, and these animals do perceive it, although not perhaps in the same way. In animals that breathe, the breath takes away something that lies on [the organ of smell] like a sort of lid, which is why they do not perceive when they do not breathe; but in non-breathing animals this is taken away, just as in the case of the eyes some animals have eyelids and cannot see unless they
25 uncover their eyes, while the hard-eyed animals do not have eyelids, which is also why they have no additional need of anything for uncovering them, but see immediately from the moment this is possible for them.

Similarly too, none of the other animals is annoyed by the odor of the things that are intrinsically malodorous, unless one happens to be destructive. And due to
30 these they are destroyed in the same way as human beings also get headaches and often are destroyed by the vapor of charcoal; in this same way, the other animals are destroyed by capacity that brimstone has and bituminous materials, and they avoid
445ª1 them because of this effect. But they are not at all concerned with the intrinsically bad odor—and indeed many plants do have bad odors—unless it contributes something to the flavor or food for them.

It seems that the perception of smell—since the perceptual modalities are odd in
5 number and an odd number has a middle—is itself in the middle between the tactile ones (touch and taste) and those that perceive through something else (sight and hearing). That is also why the smellable is an affection of things that nourish (and these belong to the tangible kind) and also of what is audible and what is visible,
10 which is why it is both in air and water that they can be smelled. So the smellable is common to both of these, and belongs to the tangible and to the audible and

43. Reading κνίπας. Cf. *HA* 534ᵇ19.

transparent. That is also why it was reasonable to have compared it[44] to a sort of dipping and washing of the dry in the wet and liquid.

Let this much be said about how one should, and should not, speak of forms of the smellable.

What some Pythagoreans claim is not reasonable; for they say that some animals nourish themselves by smells. For, in the first place, we see that nourishment must be compound; for the beings that nourish themselves are not simple either, which is also why there are residues of their nourishment, either inside them or outside, as in the plants, and since not even water is able to nourish [them] by itself, alone and unmixed (for it is necessary for what is to constitute the compound to be something corporeal), it makes still less sense to make of the air something corporeal. In addition, because there is a place in all animals that is receptive of nourishment, from which, when it is drawn in, the body takes it, while the perceptual organ for what is smellable is located in the head and the odor enters together with a breath-like exhalation, it follows that the nourishment should go into the place of respiration. That the smellable, then, insofar as it is smellable, does not contribute to nourishment is clear; that it contributes to health, however, is evident both from observation and from what has been said.

So the precise thing that flavor is in nourishment and in relation to beings that nourish themselves, the smellable is in relation to health.

Let [the objects of the perceptual modalities] with respect to each of the organs of perception, then, be determined in this way. **445b1**

6
Puzzles about Perceptible Objects

One might raise a puzzle as to whether, if every body is divisible without limit, the perceptible affections—for example, color, flavor, smell, sound, weight, cold and hot, and hard and soft—are so too. Or is this impossible? For each of them is productive of the corresponding perception (for they are all said to be so because they are capable of moving perception). So it is necessary for the perception to be divisible without limit and for every magnitude to be perceptible (for it is impossible to see something white without it having a certain magnitude). For if this were not so, it would be possible for there to be a body that has neither color nor weight nor any other affection of this sort, so that it would not be perceptible at all; for these [affections] *are* the perceptibles. Therefore, the perceptible object will not be composed of perceptible objects. But this is necessary. For it will not be composed of mathematical ones, at any rate.

44. 442b27–29.

Further, by what [capacity] will we discern and know them? Is it by means of the understanding? But they are not intelligible objects, and the understanding does not understand external objects unless it is accompanied by perception.[45] At the same time, if these things were so, it would seem to provide evidence for those who posit indivisible magnitudes; for in this way the argument would be resolved. But [indivisible magnitudes] are impossible, and we have spoken about them in our investigations concerning movement.[46]

As regards the resolution of these puzzles, it will simultaneously become clear why the kinds of color, of flavor, of sounds, and of the other perceptible objects are limited in number. For when things have extremes, what is inside them is necessarily finite. But the contraries are extremes, and every perceptible object involves contrariety—for example, in color, white and black; in flavor, sweet and bitter; and likewise in all other cases the contraries are extremes.

What is continuous, then, divides into an unlimited number of unequal parts, but into a limited number of equal ones. But what is not intrinsically continuous divides into a limited number of forms. Since, then, the affections must be regarded as forms, and there is always continuity in them, one must grasp that what is potentially and what is actively are distinct. And that is why, when we see a grain of millet, the ten-thousandth part of it escapes notice, even though the sight went over it, and the
446ᵃ1 sound within the quarter-tone escapes notice, even though one hears the entire tune, which is continuous; it is the interval of what lies in between the extreme sounds that escapes notice.

It is the same way too with the altogether small parts in the other perceptible objects; for they are visible potentially, but not actively, when they are not separated (for the foot length is potentially present in the two-foot length, but actively so when it has been separated). But if increments so small were separated, it would be reasonable if they dissolved into their environment, like a flavored droplet poured into the sea. But then, since the increment of the perception is neither perceptible by itself nor separable (for the increment is potentially present in the more exact perception), a perceptible object of that size, if separated, cannot be actively perceived either. But it will be perceptible nonetheless; for it is already so in potentiality, and it will be actively so if it is added [to an object of larger size].

That some magnitudes and affections escape notice, then, and due to what cause and in what way they are perceptible objects and in what way they are not, has now been stated. Hence, whenever certain quantities are present in [some object] in such a way that they are also actively perceptible, not only because they are contained in the whole but separate from it, it is necessary that these colors, flavors, and sounds are limited in number.

45. *DA* 432ᵃ7–10.
46. *Ph.* 6.1–2.

One might raise a puzzle: Do perceptible objects or the movements from perceptible objects (in whichever way perception comes about), when active, arrive at the middle first, as odor and sound manifestly do? For the smell is first perceived up close, and the sound reaches us after the blow. Is this also the case with what is seen and with light—just as Empedocles claims[47] that the light from the sun first arrives in the middle before it arrives at our sight or at the earth? It would seem reasonable if this happened. For what is being moved is moved from somewhere to somewhere, so that necessarily there is also a time in which it is moved from the one place to the other. But all time is divisible,[48] so that there was a time when the ray of light was not yet seen but was still spatially moving in the middle. And if every animal **446^{b}1** simultaneously hears and has heard, and, in general, perceives and has perceived, and there is no process of coming to be for them, but they exist without coming to be, nonetheless, in spite of all that, just as the sound has not yet reached the ear even though the blow has already occurred (and the change in the shape of articulate sounds shows that their spatial movement occurs in the middle; for what one hears is not what was said because the letters change their shape while the air is spatially moving), is this also the case for color and light? For it is surely not merely because they stand in a relation that one thing sees and the other is seen, like things that are equal; for in that case it would not be necessary for each of them to have a particular location. For to those things that become equal it makes no difference whether they are near or far away from each other. Or is it rather as regards sound and smell that this is reasonable? For just as in the case of air and water, the movement of both of them is divided into parts, while they are continuous in a different way. And that is why the same thing is in one way smelled by the first person and by the later one, and in another way not.

Some people think that there is a puzzle even about this. For some people say that it is impossible for one person to hear, see, or smell the same thing as another; for it is not possible for many people, since they are separate, to hear and smell [the same thing]; for that would require one and the same thing to be separate from itself. Or is it that, in the case of what first initiated the movement, for example, the bell, frankincense, or fire, all perceive one and numerically the same object, while the special perceptible [given to each of their perceptions] is distinct in number, though the same in form, which is why many people can see and smell and hear it at the same time? For these are neither bodies—but an affection and a sort of movement (for otherwise this [simultaneous perception] would not have occurred)—nor can they exist without body.

But concerning light there is another account. For light exists due to something being present [in something] but is not a movement. And, in general, things do not happen the same way in alteration and in spatial movement.

47. A57 DK.
48. *Ph.* 6.4.

For it is reasonable that spatial movements arrive first in the middle (and sound seems to be a movement of something that spatially moves), but things that undergo alteration are no longer like that. For it is possible for something to undergo alteration all at once and not one half before [the other], just as water solidifies all at the same time. Nonetheless, when what undergoes heating or solidification happens to be a large quantity, one part is affected by the part next to it, and it is necessary that the first part will change due to the thing itself that causes the alteration, and will undergo alteration at the same time all at once.

Tasting would be like smell if we lived in water and perceived [the tasteable object] from far away before making [direct] contact with it.

It is reasonable, then, to say that not all of what lies between [the perceptible object] and the perceptual organ is affected at the same time, with the exception of light, because of what we have said, and due to the same thing, in the case of seeing too; for it is light that produces seeing.

7
Perceiving More Than One Object at the Same Time

There is also another puzzle about the perceptual modalities that is as follows: Is it possible to perceive two objects together in the same undivided time, or not? Suppose, then, that the greater movement always knocks out the smaller one, which is why people do not perceive things that are brought right before their eyes, if they happen to be thinking intensely about something, or are afraid, or hear a loud noise. Let this, then, be assumed, and also that each thing can be better perceived when it is simple than when it is mixed—for example, wine that is unmixed than when it is mixed, and honey, and color, and also the highest pitch alone than together with the octave, because these things obliterate each other. And this is the effect produced by things from which some single item comes about. If, then, the greater movement knocks out the smaller, when they occur at the same time, it is necessary for that movement to be less perceptible than if it occurred alone; for the smaller movement will take away something of the larger when mixed with it, if indeed everything simple is more perceptible.

Therefore, if there are distinct movements of equal size, there will be no perception of either of them; for each will obliterate the other to the same extent, and to perceive [either of them] as simple is not possible. So either there will be no perception at all or another perception that results from both. And this is precisely what seems to occur in the case of things that are mixed, whatever the way is in which they may be mixed.

Since, then, in some cases something new emerges from [the co-occurrence of movements], while in other cases nothing new emerges, and these are the sorts of things that pertain to different perceptual modalities (for only things whose extremes

are contraries mix; for it is not possible for one thing to come about from white and high-pitched, except coincidentally, that is, not in the way in which a concord **447ᵇ1**
emerges from high-pitched and low-pitched), it follows that it is not possible either to perceive them at the same time. For if the movements are equal, they will obliterate each other, since no single movement will emerge from them; but when they are not equal, only the stronger will produce perception. 5

Further, if the soul is more likely to perceive two things at the same time by one perception if they pertain to the same perceptual modality, for example, high-pitched and low-pitched (for the movement of a single perceptual modality is simultaneous with itself to a higher degree than the movement of two, for example, of sight and hearing), and if, on the other hand, it is not possible to perceive two things with the same perceptual modality unless they are mixed (for the mixture tends to be one 10
thing, and of one thing there is one perception at the same time, and one perception occurs at the same time as itself), it follows of necessity that [only] mixed things can be perceived at the same time, because they are perceived by one active perception; for one active perception is of what is numerically one, while one potential perception is of what is one in form. Therefore, if the active perception is one, [the soul] will say that these movements are one. Therefore, they have necessarily been mixed. 15
Therefore, when they have not been mixed, there will be two active perceptions. But pertaining to one capacity and an undivided time the activity is necessarily one. For one use and movement is of one thing at once, and the corresponding capacity is one. It is not possible, therefore, to perceive two things at the same time by means of one 20
perceptual modality.

But then, if it is impossible to perceive things falling under the same perceptual modality at the same time when they are two, it is evident that it will be even less possible to perceive things at the same time if they pertain to two perceptual modalities—for example, white and sweet. For it appears that the soul expresses something's being one in number in virtue of nothing other than the simultaneity [of its perception], but [expresses] its being one in form in virtue of the [sameness 25
of the] perceptual modality discerning [it], that is, in virtue of the way [it does so]. I mean this: surely, the same perceptual modality discerns the white and the black, which are different in form; while the sweet and the bitter are discerned by a perceptual modality, which, while the same as itself, is different from the former; but though each perceives its contraries in a different way, they perceive their corresponding objects in the same way. For example, in the same way in which taste discerns the sweet, so sight discerns the white, and in the way the latter discerns 30
the black, so the former discerns the bitter. Further, if the movements of contrary **448ᵃ1**
objects are contrary to each other, and it is not possible for contraries to occur together in what is the same and undivided [time], and if contraries fall under one and the same perceptual modality, like sweet [is contrary in relation] to bitter, then it is not possible to perceive them at the same time. And it is similarly clear for the 5

ones that are not contraries;[49] for one part [of the colors] is on the side of the white, the other of the black, and similarly for the others, as some flavors are on the side of the sweet, others on the side of the bitter.

Nor can the mixed ones be perceived at the same time; for they are ratios of opposites, such as the chord of the octave and of the fifth, unless they are perceived as one. But in this way the ratio of the extremes comes about as one; but otherwise not; for then there would be at the same time the ratio of the many to the few (or of the even to the odd) and of the few to the many (or of the odd to the even).

If, then, the objects that are said to be "corresponding ones,"[50] though they are distinct in kind, are even more distant and different from each other than those that are the same in kind (I mean, for example, that the sweet and the white are corresponding, though distinct in kind, while the sweet is even more different from the black in form than the white is), it would be even less possible to perceive them simultaneously than those that are the same in kind, so that if the latter cannot be perceived at the same time, neither can the former.

As for what some of those concerned with musical concords claim, namely, that the sounds do not arrive at the same time (though they appear to do so), and it escapes our notice whenever the time is imperceptible, are they correct in claiming this or not? For perhaps, as things stand, one might also claim beyond this that it seems that we see and hear at the same time, because the intermediate times escape our notice. Or is this not true, and it is not possible for any time to be imperceptible or to escape our notice, but rather every time admits of being perceived? For if, while someone perceives himself or something else in a continuous time, it is not possible at that time for him not to notice that he exists, and if there is a time in that continuum so small that it is wholly imperceptible, it is clear that at that time he would not notice if he himself exists, and while he sees and perceives, if he perceives.

Further, there would be neither a time during which he perceives nor any object that he perceives, unless it is in this way, namely, by perceiving during a part of that time or by seeing a part of the object, if indeed there is any magnitude, whether of time or object, that is wholly imperceptible because of its smallness. For if he sees the whole line [AB], and perceives it continuously during that time in this way, namely, by perceiving in some part of that time, then let CB, during which he does not perceive it, be taken away. Surely, then, he perceives during some part [of this remaining time] or he sees some part of [the line], just as he sees the whole earth, because he sees this particular part of it, and as he walks during a whole year, because he walks during this particular part of it. But during part CB he perceives nothing. Therefore, it is by means of perceiving during a part of the time, and by perceiving a part of AB, that he is said to perceive the whole AB and the whole line. And the same argument

49. I.e., the intermediate ones, which, in the case of colors, belong to the black if black predominates in them, and to the white, if white does.
50. 447b30.

applies to AC as well. For his perception is always during some part and of some part, but the whole ACB cannot be perceived.

All [magnitudes] are perceptible, then, but do not appear to have the magnitude they have. For one sees the magnitude of the sun and of the four-cubit object from afar, but they do not appear to be of that size, but sometimes they appear to be indivisible, but one does not see an indivisible object. The cause was stated in the previous discussion concerning this issue.[51] That there is no imperceptible time, then, is clear from this.

But the previously mentioned puzzle must be investigated, as to whether it is possible or not possible to perceive a plurality of objects at the same time. By "at the same time" I mean in one and indivisible time in relation to each other.

First, then, is it possible in this way, when they are perceived at the same time but with a distinct part of the soul, and not in an indivisible time, but in one that is invisible in the sense that the whole is continuous? Or, is it that, first, with regard to the objects of one perceptual modality (I mean, for example, sight), if the soul perceives one color with one part and another color with another part, it will have a plurality of parts that are the same in form (for what it perceives is in the same kind)? But if someone were to claim that, as there are in fact two eyes, nothing prevents this from also being the case in the soul, one must reply that presumably from these one thing emerges, and so the activity of these is one; but here [in the soul], if one thing emerges from both, this will be what perceives, but if they are separate, the two cases will not be alike. Further, perceptual modalities that are the same will be many in number [because their activations are many], as if one were to declare indistinguishable sciences [to be many, on the same grounds]. [But this is not possible.] For the activity will not exist without its corresponding capacity, nor will there be perception without this capacity.

But if *this* object is perceived in one indivisible time, it is clear that the other objects will be too. If, then, the soul perceives sweet with one part and white with another part, what results from them will either be one or not one. But it must be one. For the part capable of perception is one part [of the soul]. What, then, will its one corresponding object be? For no single object is composed of these.[52] It is necessary, therefore, that there will be one part with which the soul perceives everything, as was said previously,[53] but one kind through one part [of it], another through another.

Is the capacity to perceive sweet and white—insofar as it is actively undivided—one thing, then, but distinct [ones] whenever it becomes actively divided? Or is what is possible in the case of things themselves likewise possible in the case of the soul as well? For what is white and sweet, and many other things too, is numerically one and the same thing. For, if the affections of things are not separate from each other, the

51. $445^{b}3$–$446^{a}20$.
52. I.e., white, sweet, and so on.
53. *DA* $426^{b}23$–$427^{a}14$.

being, however, is distinct for each of them. Therefore, we should similarly posit also in the case of the soul that the part capable of perceiving everything is numerically one and the same but the being for it is distinct—in kind in the case of some things, in form in the case of others. So the soul perceives [a plurality of objects] at the same time and with a part that is the same and one, but not the same in account.

That every perceptible object is a magnitude, and that there is no indivisible perceptible object, is evident. For the distance from which an object could not be seen is without limit, but the distance from which it can be seen is limited. And similarly also in the case of smellable objects, audible objects, and all the objects we perceive without [direct] contact. There is, then, a last point of the distance from which the object is not seen and a first one from which it is seen. This point, beyond which it is not possible to perceive that the object exists and before which the object is necessarily perceived, must be indivisible. If, then, there is an indivisible perceptible object, whenever it is placed at the extreme point from which it last cannot be perceived and first can be perceived, it will turn out to be visible and invisible at the same time. But this is impossible.

449b1 The perceptual organs, then, and the perceptible objects, what way things stand with respect to them both in common and in regard to each perceptual organ, have now been spoken about. Of the remaining issues, memory, remembering, and sleep must be investigated first.

ON MEMORY AND RECOLLECTION*

1
Definition and Explanation of Memory

Concerning memory and remembering we must say what it is, due to what cause it occurs, and to which part of the soul both this affection, and also recollection, belong. For it is not the same people who are good at remembering and at recollecting, but for the most part those who are slow are good at remembering, while those who are quick and learn with ease are better at recollecting.

First, then, we must grasp what sorts of things can be remembered; for often there is error about this. For neither is it possible to remember the future—which is rather the object of belief or of expectation (and there might even exist a science concerned with expectation, just as some people say that the craft of prophecy is)—nor is it possible to remember the present, but only to perceive it, because with perception we know neither the future nor the past but only the present. Memory, however, is of the past. As for the present while it is present, nobody would say that he remembers it—for example, this particular white thing while he sees it. Nor would he say that he remembers what he contemplates while engaged in contemplation and understanding; instead, of the former he would say only that he perceives it, and of the latter only that he scientifically knows it. But whenever he possesses the scientific knowledge or the perception without their actual objects, then he remembers that he has learned or contemplated that the angles of the triangle are equal to two right angles, or that he has heard or seen it or something like that. For always when he is actively remembering he says in his soul that he has heard, perceived, or understood it before.

Memory, then, is neither perception nor supposition but rather a state or an affection of one of these when time has passed. Of the now, and in the now, there is no memory, as was said,[1] but of the present there is perception, of the future there is expectation, and of the past there is memory. That is why all memory involves time. So only those animals that perceive time can remember and [they do this] by means of that by which they perceive it.

* Translated by Klaus Corcilius. Text: As for *De Sensu*.

1. 449^{b}13–18.

Further, we have spoken about imagination previously in the *De Anima*,[2] and understanding is not possible without an appearance[3]—for in understanding precisely the same thing happens as in drawing a figure. For in drawing it, even though we do not make use of the fact that the triangle is of a determinate quantity, we nontheless draw it as having a determinate quantity; and in the same way a person who is understanding, even when he does not understand something quantitative, puts something quantitative before his eyes, but does not understand it insofar as it is a quantity. And when the nature of what he understands belongs to quantitative things, but of indeterminate size, he posits it as a determinate quantity but understands it only insofar as it is a quantity.

Due to what cause it is not possible to understand anything without a continuum nor without time is a matter for another account.[4] But it is necessary that one knows magnitude and movement by the same means by which one also knows time, and the appearance is an affection of the common perception, so that it is evident that the knowledge of them is by means of the primary perceptual capacity. And memory, including the memory of intelligible objects, is not possible without an appearance. So memory belongs to the understanding part coincidentally, but intrinsically to the primary perceptual capacity. That is also why it belongs to some of the other animals and not only to the human being, that is, to those that possess belief or thought.[5] And if memory were one of the understanding parts, it would not occur in many of the other animals, and perhaps in none of the mortal animals, since, even as things stand, it does not belong to all of them because not all of them have a perception of time. For always, when one is active with one's memory, just as we have said previously,[6] one additionally perceives that one knew this or heard or experienced it before, and the before and after are in time.

To which part of the soul memory belongs, then, is evident: it belongs to precisely the part to which imagination also does. And the intrinsic objects of memory are the things of which there is imagination, and the coincidental objects of memory are all those that are not without imagination.[7]

One might raise a puzzle as to how one may ever, while the affection is present and the object absent, remember what is not present. For it is clear that one must understand the affection that takes place in the soul through perception, and in the part of the body that possesses it, like a sort of picture, the having of which we call "memory." For the movement which comes about is impressed like a sort of imprint of the perceptual affection, like those who seal documents with their signet rings make.

---

2. 3.3.
3. *DA* 431a17.
4. *DA* 3.6.
5. *HA* 588a18–b3, *GA* 753a11–17.
6. 449b19–23.
7. I.e., intelligible objects.

That is also why in some people who are much in movement, due to feeling or to young age, the imprint does not come about, just as if the movement or the seal **450ᵇ1** were to encounter running water; while in others, because they are worn away like old buildings, and because of the hardness of what is to receive the affection, the imprint does not enter in the first place. That is why those who are very young and those who are old are forgetful; for they are in flux, the young on account of their growth, the old on account of their withering away. And, similarly, neither the exceedingly quick nor the exceedingly slow appear to have good memory, because the former are wetter, and the latter are harder than what is needed. In the case of the young, then, the appearance does not remain in the soul, while in the case of the old it does not take hold.

But if this is indeed what happens with regard to memory, does one remember the affection or the thing from which the affection originated? For, if the former, we would not remember any of the things that are absent; and if the latter, how do we, while we perceive, remember what we do not perceive, namely, what is absent? And if it is like an imprint or a picture in us, why would the perception of it be a memory of something else and not of that imprint or picture itself? For the person who is active with his memory contemplates this affection and perceives it. How, then, will he remember what is not present? For then it would also be possible to see what is not present or to hear it.

Or is there a way in which this is possible and does happen? For just as a picture drawn on a panel is both a picture and a likeness, that is, one and the same thing is both of these, yet the being is not the same for both, and it is possible to contemplate it both as a painting and as a likeness, so in this same way one should also suppose that the appearance in us is both something intrinsically and the appearance of something else. Insofar as it is intrinsically something, then, it is an object of contemplation or an appearance, and insofar as it is of something else, it is like a likeness and an object of memory. So too whenever the movement belonging to the appearance is active, and the soul perceives it in the way it is intrinsically, it appears to enter [the soul] like an object of thought or an appearance; if, on the other hand, it [perceives it] as of something else and like a picture, the soul contemplates it as a likeness, and, even though it has not seen Coriscus, contemplates it as Coriscus. In this latter case, the experience of the contemplation is other than when the soul contemplates [the appearance simply] as a drawn picture, and in the soul the latter occurs like an intelligible object only, while in the former way, because it is a likeness, **451ᵃ1** it occurs as an object of memory.

And that is why we sometimes do not know, when movements of this sort occur in our soul due to prior perception, or whether they are in accord with our prior perception, and sometimes we are in doubt whether this is a memory or not. And sometimes it happens that we think and recollect that we have heard or seen something before. This occurs whenever one changes, while contemplating something as itself, and contemplates it as of something else. The contrary happens sometimes as well, as it happened to Antipheron of Oreos and to other deranged people; for they spoke

of their appearances as of past events and as if they were remembering them. This happens whenever one contemplates what is not a likeliness as if it were a likeness.

Mnemonic exercises preserve memory by means of repeated recollection. This is nothing other than often contemplating [an image] as a likeness and not as it is in itself.

What memory and remembering is, then, has been stated: it is the having of an appearance as a likeness of what it is an appearance of, and also to what part in us it belongs, namely, the primary perceptual one,[8] that is, the one by means of which we perceive time.

2
Definition and Explanation of Recollection

It remains to speak about recollecting. First, then, everything that is true in the tentative discussions[9] must be set down as facts. For recollection is neither the recovery of a memory nor is it its acquisition. For when one learns or is affected for the first time, one neither recovers any memory (for there was none before), nor does one acquire it from the start; for it is when the state or affection has come about in one that there is memory, so that it does not come about together with the affection that has come about.

Further, when [the affection] has come about for the first time, in that indivisible and ultimate moment, the affection is already present in the person thus affected, that is, the scientific knowledge, if one must call the state or the affection "scientific knowledge" (and nothing prevents us from also coincidentally remembering some of the things that we know). But the remembering as such does not exist before time has passed; for one remembers now what one has seen or experienced before, one does not remember now what one has experienced just now.

Further, it is evident that it is possible for someone to remember something without having recollected it just now, but rather having perceived or experienced it from the start. But whenever one recovers the knowledge or perception one had before (or whatever we said[10] it is the having of which is memory), this is [recollection] and then the recollecting of one of the items just mentioned can take place, the remembering occurs and the memory follows.

But surely these things are not [recollected] unconditionally when, having been previously present in one, they come about in one again; rather, in a way they are, and in another way they are not. For it is possible for the same person to learn and discover the same thing twice. Recollecting, then, must be different from such cases, and recollecting must require the presence of a richer starting-point than the one from which they learn [the same thing for a second time].

8. *DA* 422b23, 424a25.
9. Reference unclear.
10. 451a15–16.

Recollections take place when one movement naturally occurs after another. For if this happens of necessity, it is clear that whenever the first movement occurs, the second movement will occur, and if not of necessity, it will occur for the most part. It happens that some people become more habituated by being moved just once than others by having been moved many times. That is why we remember some things better, even though we have seen them only once, than others that we have seen many times.

Whenever we recollect, then, we are moved by a certain one of the antecedent movements, until we are moved by a movement that is habitually followed by that one. That is also why we hunt [for the latter] using what comes next in sequence by proceeding in our understanding from the present or from some other time, and from what is similar, or contrary, or close to the one we are searching for.

That is why recollection occurs; for some of the movements of these things are the same [as the one sought], some of them occur at the same time, and some of them have a part of it, so that little remains for one to be moved by after it. People search, then, in this way, and even when they are not searching, they recollect in this way, whenever the movement they are searching for occurs after another. But for the most part the movement they are searching for occurred after other movements of the sort we mentioned have occurred.

And one must not investigate how we recall what is distant from us, but what is nearby; for it is clear that the way [of finding the movement] is somehow the same. What I mean [by "what is nearby"] is what is next without having previously searched for or recollected [it]. For the movements follow each other through habit, this one after the other, and whenever one wishes to recollect, therefore, this is what one will do: one will seek to get hold of a starting-point of movement, after which the one sought will occur.

That is why recollections that begin from a starting-point occur in the quickest and best way. For as the things stand in relation to each other with regard to their **452^{a}1** sequence, so too do the movements. And all movements that have a certain order are easy to remember, such as mathematical objects, while those that are poorly ordered are difficult to remember.

Also, recollecting is different from relearning in that one will be capable somehow of being moved by oneself toward what comes after the starting-point. But whenever this is not the case, and one is moved by something else, one is no longer reminding oneself. Often, though, one is incapable of recollecting something immediately, but when one searches, one is capable and finds it. And this happens when one brings about many movements, until one causes the sort of movement that is followed by the thing one is searching for. For reminding oneself consists in the internal presence of the capacity to cause movement; and this in such a way as to be moved by oneself, that is, from the movements one possesses, as was said.

But one must get hold of a starting point. That is why people sometimes seem to recollect from places.[11] The cause is that they move quickly from one thing to the

11. E.g., in a mnemonic device.

other—for example, from milk to white, from white to air, and from this to wet, from which one recalls fall, which was the season one was searching for.

The universal seems to be a starting-point and the middle in all cases; for if one does not do so before, one will remind oneself whenever one arrives at this middle point, or else one no longer knows from where else to start. For example, suppose one understands the sequence as marked by A B C D E F G H [Fig. 1].

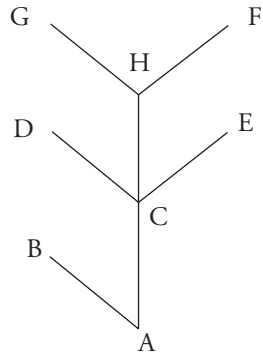

Fig. 1

For if one has not reminded oneself at C—for from there it is possible to be moved both toward D and toward E—and if one was not searching for one of them, one will remind oneself when one arrives at H, if one is searching for G or F. And one keeps going in this way.

The cause of our sometimes reminding ourselves from the same starting-point and sometimes not is that it is possible to be moved in a plurality of directions from the same starting-point—for example, from C toward E or D. Whenever, then, we are moved after a very long time, we will move toward what is more habitual; for habit is already like nature. That is why we recollect quickly the movements we do frequently; for just as one thing comes after another by nature, so also do activities. And frequency [in the activities we engage in] produces a nature.

But since in nature things happen both contrary to nature and by luck, and this happens even more so in movements due to habit, which, at any rate, are not equally natural, so that sometimes one is not moved in that direction [in which one wishes to be moved], especially if one pulls oneself away from there. That is why, when we need to remember a name which is similar to a name we know, we commit a slip of the tongue with respect to it.[12]

Recollection, then, comes about in this way. Most importantly, however, one must know the time [that has elapsed], either by a measure or indeterminately. But there

12. E.g., saying "Cathleen" for "Catherine."

was something by which one discerned the greater and lesser time.[13] It is reasonable that this takes place in the same way in which one discriminates magnitudes. For one understands magnitudes as great and distant not by stretching out one's thought to the object, as some people[14] claim we stretch out our sight (for one can in the same way understand non-existent things), but by a proportional movement; for in it there are similar shapes and movements.

In what way, then, will it be different when one understands larger objects? Is it that one understands the [internal objects], which are smaller (for all internal objects are smaller), and, proportionally, the external objects as well? Perhaps, then, just as with [perceptual] forms, it is possible to take something proportional, but inside oneself, so also with their distances. Thus, if one is moved in movement AB and BE [Fig. 2], one produces[15] CD, for AC and CD are proportional.

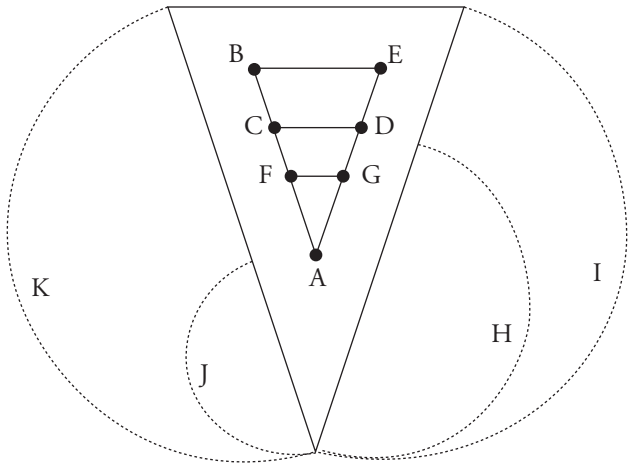

Fig. 2

Why, then, does one produce movement CD rather than FG? Or is it because AC is to AB as H is to I? And one is accordingly also simultaneously moved in these movements. And if one wishes to understand FG, one will in that same way understand BE, and instead of HI one will understand JK. For they are related as FA is to BA.

Thus, whenever the movement of the sought object occurs simultaneously with that of the time, then one is active with one's memory. And if one merely thinks one is, but one is not producing [these movements], one merely thinks that one remembers. For nothing prevents someone from being mistaken and believing that he is remembering when he is not remembering. But to be active with one's memory and not to think so, and to remember without noticing it, is not possible; for that very

13. 449ᵇ28–30.
14. *Sens.* 437ᵇ9–438ᵃ5.
15. I.e., represents by way of.

thing was the remembering. But when the movement of the object occurs without the movement of the time, or the latter without the former, one does not remember.

The movement of time is twofold. For sometimes one does not remember the time in terms of a measure, for example, that it was three days ago (one does, however, remember that one did something at some time), and sometimes one remembers the time in terms of a measure. But one remembers even when it is not in terms of a measure. And people are accustomed to say that they remember something, but do not know when [it occurred], whenever they are unaware of the quantity of time in terms of a measure.

That not the same people are good at remembering and at recollecting was stated previously.[16] But remembering is different from recollecting not only with respect to time but in that many of the other animals have a share in remembering as well, but (one might almost say) none of the known animals has a share in recollecting, except for the human being. The cause of this is that recollecting is like a sort of deduction. For one who recollects deduces what he previously saw, heard, or was affected by in some such way, and it is like a sort of search. And by nature it occurs only in those animals that also have the deliberative capacity; for deliberating too is like a sort of deduction.

A sign that the affection is something bodily, and that recollection is a search for an appearance in this domain, is that some people get troubled when they cannot recollect in spite of having directed their thought to it, and also when they nonetheless recollect even when they are not trying anymore, and this is especially the case with impulsive people, for the appearances move them most intensely. The cause of its not being up to them is this. Just as it is not any longer up to those who throw a ball to make it stop, in this same way too the person who is recollecting and hunting for something sets in movement a sort of bodily affection. Most troubled by this are those who happen to have liquid around the place of the perceptual part; for the liquid does not easily stop moving, until what they seek returns and the movement proceeds in a straight course. That is why episodes of anger and fear, when they cause such movements, do not calm down in spite of reverse contrary movements [of those who undergo these movements], but set up countermovements in the same direction. This affection is like when some name, tune, or saying is very much on one's lips. For even though having stopped ourselves, and having no wish to, it comes upon us to sing it or say it again.

Those who have larger upper bodies and those who are dwarf-like have poorer memory than those with the contrary stature, because much weight rests on their perceptual part, which means that from the start the movements cannot stay but dissolve instead, and they also do not easily move in a straight course during recollection. Those who are altogether young and exceedingly old are forgetful because of the movement involved; for the latter are withering, the former growing very rapidly. Further, children are also dwarf-like until they advance in age.

Memory and remembering, then, what their nature is and by means of which part of the soul animals remember, and also recollecting, what it is, how it occurs, and due to what cause, have now been spoken about.

16. 449b6–8.

ON SLEEP AND WAKING*

De Somno et Vigilia

1
Introduction

As regards sleep and waking it must be investigated both what they are and whether they are special to the soul or to the body, or common to both; and if they are common to both, to which part of the soul or of the body they belong, and due to what cause they belong to the animals. Also, whether all animals share in both of them, whether some share in sleep alone and others in the other alone, or whether some share in neither and some others in both. In addition, it must be investigated what a dream is, and due to what cause those who are asleep sometimes dream and sometimes do not dream, or whether it so happens that those who are asleep always dream but do not remember it, and if this happens, due to what cause it happens. Also, whether it is possible or not possible to foresee what will happen in the future, and if it is possible in which way; and whether only those future things that are done by human beings can be foreseen or also those for which the daimonic is the cause, and come about by nature or spontaneously.

That waking and sleep belong to the same part of the animal is evident. For they are opposed to each other and it seems that sleep is some sort of privation of waking. For the extreme opposites, both in others and also in natural things, manifestly always occur in the same recipient, that is, they are affections of the same thing. I mean, for example, health and disease, beauty and ugliness, strength and weakness, seeing and blindness, hearing and deafness. Further, this is also clear from the following. For what we recognize whether someone is awake by is **454ª1** also what we recognize whether he is asleep by. For we think that the one who is perceiving is awake, and that the one who is awake is perceiving either one of the external things or one of the movements that take place in himself. If to be awake, therefore, lies in nothing other than in perceiving, it is clear that it is by virtue of the very same thing that those who are awake are awake and that those who are asleep are asleep. And since perceiving is neither special to the soul nor to the body (for what the capacity belongs to the actuality belongs to as well, and what is called perception in actuality is a sort of movement of the soul through the body), it is evident that the affection is neither special to the soul nor is it possible for a soulless body to perceive.

* Translated by Klaus Corcilius. Text: As for *De Sensu*.

Since we have made our distinctions previously elsewhere[1] about what are called "parts" of the soul, and the nutritive part was separated from the other parts in the things that possess life, while none of the other parts can exist without it, it is clear that all living things that participate only in growth and withering possess neither sleep nor waking, such as the plants (for they do not have the perceptual part, whether it is separable or not separable; for it is separable in capacity and in being).

Likewise it is clear too that there is nothing that is always awake or always sleeping; rather, both of these affections belong to the same animals. For if there is an animal that does not possess perception, it is not possible for it to sleep or to be awake (for both of these affections have to do with a disposition of the primary perceptual part); nor is it possible for one of them always to belong to the same animal—for example, a kind of animal that always sleeps or a kind that is always awake.

Further, for everything that has a natural work, whenever it exceeds the time [for its exercise], or for doing one of the things that it is capable of doing, it must become incapacitated—for example, the eyes when they see for too long, and so cease doing this; and likewise the hand too, and everything else that has a work. If, then, to perceive is the work of something, this too, when it exceeds the time during which it was capable of perceiving continuously, will become incapacitated and will not do it any longer.

If, therefore, to be awake is defined by the release of perception [from sleep], and, among contraries, it is necessary for one of the two to be present and the other not, if to be awake is contrary to sleeping, and it is necessary for one of the two to belong to every animal, then sleeping is necessary. If this sort of affection is sleep, then, and it is an incapacity due to an excess of being awake, and the excess of being awake is sometimes connected to illness and sometimes occurs without illness, so that the incapacity and its release will occur in the same way, it is necessary that every animal that is awake can sleep. For it is impossible to be always active.

Nor, similarly, can any animal always sleep. For sleep is a certain affection of the perceptual part, like a sort of fetter and inability to move, so that it is necessary for every animal that sleeps to possess the perceptual part. But a perceptual part is what is capable of perceiving in actuality. And it is impossible to be active with one's perception in the strict sense and unconditionally and at the same time to sleep. That is why it is necessary that all sleep admits of awaking.

Pretty much all other animals clearly have a share in sleep, whether swimming, winged, or footed. For in fact the kinds of fishes and of the soft-bodied animals have been observed sleeping, and also all other animals that have eyes; for even the hard-eyed animals and the insects manifestly do sleep, but all these animals have short sleeps, which is why one might often not notice whether they participate in sleep or not. As for the hard-shelled animals, it has not yet become clear to observation whether they sleep. But if the argument we have advanced is persuasive to anyone, he will be persuaded by it.

1. *DA* 2.2–3, 3.9.

That all animals have a share in sleep, then, is evident from the following. For the animal is defined by the possession of perception, and we say that sleep is in some way the inability of perception to move, like a fetter, whose release and loosening is waking. But none of the plants is capable of having a share in either of these affections. For without perception there is neither sleep nor waking. And those who possess perception also possess pain and pleasure, and those who possess these also possess appetite. But plants have none of these. A sign of this is that the nutritive part does its work more during sleep than during wakefulness. For then animals nourish themselves and **455ᵃ1** grow more, which suggests that they do not need perception for these tasks.

2
Why Sleeping and Waking Occur

Why animals sleep and are awake and due to which sort of perceptual modality, or which sorts if it is due to several of them, must be investigated. Since, then, some animals possess all the perceptual modalities, and some do not possess sight, while all possess touch and taste, except if one of the animals is incomplete (we have spoken about this in the *De Anima*[2]) and it is impossible for an animal unconditionally to perceive with any of the perceptual modalities whatever while asleep, it is evident that the same affection necessarily belongs to all perceptual modalities during what is called "sleep." For if the affection belongs to one perceptual modality but not to another, the animal will perceive with the latter while asleep, which is impossible.

Since each perceptual modality has something special to it, and also something common—for example, special to sight is seeing, and to hearing to hear, and the same account applies to the other perceptual modalities. But there is also a common capacity, one that goes along with all these, and with which one also perceives that one sees and hears. For it is clearly not with the sight that one sees that one sees, and it is also clearly neither by way of taste nor sight nor with both that one discerns, and is capable of discerning, that sweet things are distinct from white things, but rather with a certain part that is common to all perceptual capacities. For there is one perception, and the controlling [perceptual organ] is one, but the being for perception is distinct for each kind—for example, of sound and of color. And [this common capacity] occurs above all together with the capacity of touch. For this can be separated from the other perceptual organs, whereas the others are inseparable from it. (We have spoken about these things in our observations in the *De Anima*.[3]) It is evident, therefore, that waking and sleep are affections of this common capacity. That is also why it belongs to all animals; for touch alone also belongs to all.

2. 425ᵃ10–11, 432ᵇ20–25.
3. 413ᵇ4–10, 414ᵃ2–4, 415ᵃ3–6, 435ᵃ12–14, ᵇ2.

For if sleep came about by way of an affection of all the perceptual modalities, it would be strange if those perceptual modalities, for which it is neither necessary nor possible in a certain way to be active at the same time, were necessarily inactive and immovable at the same time. For it would make more sense if the contrary happened to them, namely, not to be at rest at the same time. And the way we now speak is reasonable also in regard to this. For when the perceptual organ that controls all the others, and toward which the others are directed, undergoes some affection, it is necessary that the remaining ones are all affected along with it, while when one of the latter is incapacitated, it is not necessary for it to be incapacitated.

It is evident from many considerations that sleep does not consist in the inactivity of the perceptual modalities, in our not employing them, and also not in not being able to perceive. For something of this sort also happens in cases of fainting; for a faint is an incapacity of perception, and there are also states of unconsciousness of this sort. Further, those whose blood vessels in the neck are squeezed become insensible. But rather [sleep occurs] whenever the incapacity of its employment takes place neither in a random perceptual organ nor due to a random cause, but, as has just been said, in the primary perceptual one with which one perceives all things. For whenever this is incapacitated, it is necessary for all the perceptual organs to be incapable of perceiving too, but whenever one of these is incapable, it is not necessary for the primary perceptual one to be so.

Due to what cause sleeping comes about, and what sort of affection it is, must now be stated. For we call the for-the-sake-of-which, the starting-point from which the movement arises, the matter, and the account a "cause."

First, then, since we say that nature acts for the sake of something, and this is some good, and rest is necessary and beneficial for every creature that is by nature moved and not capable of moving always and continuously with pleasure, and since people, due to the truth itself, apply to sleep the metaphor of being a "rest," it follows that it exists for the sake of the preservation of the animals. Waking, though, is the end. For perceiving and thinking are the end for all that possess either of them. For they are the best, and the end is what is best. That sleep of necessity belongs to each of the animals is clear. I mean, hypothetical necessity,[4] because if there is going to be an animal that possesses its own nature, of necessity certain things must belong to it, and if these things belong, other things must belong.

Further, which sort of movement and action occurring in their bodies produces waking and sleeping in animals must next be discussed. We must suppose, then, that their causes in other animals are just like (either the same or analogous) the ones in the blooded animals, and in the blooded animals just like in the human beings, so that it is on the basis of the latter that we must get a theoretical grasp on all of them.[5]

4. *PA* 639b19–640a8.
5. *HA* 491a19–23.

That the starting-point of perception is from the same part from which the movement also arises has been determined earlier elsewhere.[6] And of the three places that **456ᵃ1**
have been distinguished this is the one in the middle between the head and the lower stomach. In blooded animals this is the part around the heart. For all blooded animals have a heart, and the starting-point of movement and of the controlling 5
perception is located there.

As for movement, it is evident that the starting-point of breath and, in general, that of cooling is located there, and that it is with a view to preserving the heat residing in this part that nature has provided beings that breathe and cool themselves by means of liquid. But we will speak about this by itself later on.[7] 10

In bloodless animals, insects, and those that do not take in breath, it is in the analogous part that their innate breath is observed puffing up and sinking down. This is also clear in the case of the whole-winged insects, such as wasps and bees, and in flies and other animals of this sort. And since it is impossible to move anything or to produce anything without strength, and what produces strength is the holding of one's 15
breath—in the case of those animals that breathe in, this is the holding of the breath from outside, while in the case of animals that do not breathe, it is the holding of the innate breath (that is also why the winged insects are observed to buzz when they move because of the breath rubbing against the diaphragm of the whole-winged insects), and all animals move themselves as a consequence of some perception, either proper or 20
alien,[8] in the primary perceptual organ—then, if sleep and waking are affections of this part, it is evident in which place and in which part sleep and waking primarily occur.

Some people, though, move while they are sleeping and do many things that are characteristic of wakefulness,[9] but they do not do this without an appearance and a sort of perception. For a dream is in a way a perceptual affection. But we must speak about 25
this later on.[10] Why these people remember their dreams when they are awake, but do not remember the actions characteristic of wakefulness, has been stated in the *Problems*.[11]

3
The Efficient Cause of Sleep

Next after what has been said it is to discuss in what sorts of circumstances and from 30
what source the affection of waking and sleeping arises. It is evident, then, that since it is necessary for the animal, as soon as it has perception, to first take in nourishment

6. *PA* 665ᵃ10–15, 666ᵃ11–13 mention this fact, but 647ᵃ24–27 and 656ᵃ27–30 seem to refer to the present discussion.
7. *Juv*. 14, 19.
8. I.e., internal or external.
9. *GA* 779ᵃ16–19.
10. *Insomn*. 3.
11. Not in the extant †*Pr*.

and to grow, and the last stage of the nourishment for all blooded animals is the nature of the blood, and its analog for the bloodless animals, and the place of the **456ᵇ1** blood is the blood vessels, and the starting-point of them is the heart (what we say is evident from the *Dissections*)—thus, while the nourishment from outside arrives in the places that are receptive of it, the vapor arising from it gets into the blood vessels, and there it undergoes a change, turns into blood, and proceeds toward its starting-point.

We have spoken about these things in *On Nourishment*.[12] But now we must take them up again for the sake of getting a theoretical grasp on the starting-points of the movement and how the perceptual part is affected when waking and sleeping occur. For sleep is not any random sort of incapacity of the perceptual part, as was said.[13] For unconsciousness, a sort of choking, and fainting also produce some such incapacity. In fact, to some people an appearance has even occurred during a deep faint.

But this involves a certain puzzle. For if it is possible that someone who has fainted has fallen asleep, it is possible that the appearance is a dream. And there are many things that those in a deep faint and who are believed to have died report, about all of which one must suppose that the same account holds. However, as we have said, sleep is not every incapacity of the perceptual part, but this affection comes about from the exhalation that rises in connection with nourishment. For the product of the exhalation is necessarily pushed up to a certain point, and then it must turn and change its course like the tide in a narrow strait. And the hot material of each of the animals is naturally carried upward. But when it reaches the upper places, it turns back in a mass and is carried downward. That is why fits of sleepiness start most often after nourishment. For much of the wet and corporeal material is carried upward in a mass. When, then, it comes to a stop, it weighs one down and makes one doze off. And when it turns, sinks downward, and pushes away the hot material, then sleep comes about and the animal sleeps.

The things that induce sleep are also a sign of this; for they all make the head heavy, both the drinkable and the eatable ones—poppy, mandrake root, wine, and darnel. And people who are weighed down [by sleep] and doze off seem to be affected in this way, and they are incapable of lifting their heads and their eyelids. And it is most of all after eating food that sleep is of this sort. For after meals there is a large quantity of exhalation from the food. Further, it comes from certain sorts of fatigue. For fatigue has a liquifying effect, and the product of that liquification, unless it is cold, acts like unconcocted nourishment. Also, some diseases produce the same **457ª1** effect, namely, all those that originate from a wet and hot residue, as it happens, for example, in those who have a fever or are lethargic.

Further, early childhood. For infants sleep a lot because the whole nourishment is carried upward. A sign of this is that the size of the upper parts exceeds that of the

12. Cf. *PA* 650ᵇ8–11.
13. 455ᵇ2–13.

lower parts during early childhood, because growth goes in that direction. Due to the same cause they are also prone to epilepsy. For sleep is similar to epilepsy and is in a way a sort of epilepsy. That is also why the starting-point of that affection occurs to some people while they are asleep, and they have seizures while sleeping, but not while awake; for when a large quantity of breath is carried upward, when it comes down again it makes the blood vessels swell and compresses the ducts through which breathing takes place. That is why wines are not advantageous to small children, nor to their wet nurses (for presumably it makes no difference whether they drink it themselves or their wet nurses do); on the contrary, they should drink them mixed with water and in small quantities; for wine is breath-like, in particular dark wine. The upper parts are so full of nourishment in small children that they do not turn their neck for five months; for just as in the very drunk a large quantity of liquid is carried upward. And it is reasonable that this affection is also the cause of the fetuses remaining at rest in their mother's uterus at first.

Also, in general, those who have inconspicuous blood vessels are prone to sleeping and also those who are dwarf-like or have large heads; for the blood vessels of the former are narrow, so that it is not easy for the liquid to flow downward, while in dwarf-like people and in those with large heads the upward impulse of the exhalation is great. Those who have large blood vessels, however, are not prone to sleeping, because of the free passage their vessels allow, unless they have some other contrary affection.

Nor are impulsive people (*melagcholikoi*) prone to sleep; for their inner place has been cooled down, so that no large quantity of exhalation comes about in them. That is also why they are voracious eaters though they are thin; for their bodies are so disposed as not to receive any benefit from it. And the black bile (*melaina cholê*), since it is cold by nature, also makes the nutritive place and the other parts of the body cold, wherever this sort of residue is potentially present.

So it is evident from what was said that sleep is a sort of assembling of the hot in the inward direction and a natural reciprocal replacement [of hot with cold material] due to the cause that was stated.[14] That is why there is a lot of movement in a sleeping person. And the place where the heat leaves from grows cold and, on account of the cooling, the eyelids fall close, and the upper and external parts grow cold, while the internal and lower parts are hot—for example, the parts around the feet and the internal parts. **457b1**

And yet one might raise a puzzle about the fact that sleep is deepest after meals, and that wine and other such things that possess heat are sleep-inducing, though it does not make good sense that sleep should be a process of cooling, while the causes of sleeping are hot.

Does this, then, happen because just as the stomach is hot when empty, and the filling cools it down because of the movement, so too the ducts and places in the head are cooled down when the exhalation is moving upward? Or is it that just as people

14. 456b17–28.

who have hot material poured over them shiver immediately, so too here when the heat moves upward the cold gathers together, cools down, and makes what is hot by nature lose its power and withdraw?

Further, when a large quantity of nourishment comes in, which the heat draws upward, it—like a fire when logs are placed on it—cools down, until it has been concocted. For, as was said,[15] sleep comes about when the corporeal exhalation is carried upward by the heat through the blood vessels in the direction of the head. And when what has been drawn upward cannot keep going upward, but is excessive in quantity, it is pushed back again and flows downward. That is also why human beings fall down when the heat raising them up is withdrawn from under them; for the human being alone among the animals stands upright. And when it befalls them it first produces a loss of consciousness, and later an appearance.

Or is it rather that, while the resolutions of the puzzles given just now are possible explanations for the coming about of the cooling process, nonetheless it is the place that is really in control, as has been stated elsewhere,[16] and the brain is the coldest of all the parts of the body, and for those animals that do not possess a brain it is the analog? Just as the moisture, then, that evaporates due to the heat of the sun, when it comes to the upper region is cooled down due to its coldness, and having been condensed is carried down once it has become water again, in that same way during the rise of the heat toward the brain the exhalation from the residue gets composed into phlegm[17] (which is also why mucus is observed to arise from the head), and the nutritive and non-diseased exhalation is carried downward after it gets composed and cools the heat. The thinness and narrowness of the blood vessels around the brain contributes to its cooling and not easily receiving the exhalation. This, then, is the cause of the cooling, despite the fact that the exhalation is exceedingly hot.

One wakes up, though, whenever [the nourishment] has been concocted and a large quantity of heat, after having been forced together from the surroundings into a small space, gets the upper hand and the more corporeal blood has been disaggregated from the purer blood. And the finest-grained and purest blood is in the head, while the coarsest-grained and thickest is in the lower parts. But the starting-point of all blood, as has been stated both here and elsewhere,[18] is the heart.

Of the cavities of the heart, the one in the middle is common to each of the other two, and each of them receives [its blood] from each of the two blood vessels, the so-called great vessel and the aorta, while the disaggregation takes place in the middle cavity. But to make determinations about these issues more properly belongs to other accounts.[19] Sleep occurs because the blood becomes more disaggregated after the intake of nourishment, until the purer blood is disaggregated into the upper places

15. 456ᵇ20–24.
16. *Sens.* 444ᵃ10–15, *PA* 652ᵃ24–653ᵇ8.
17. *GA* 725ᵃ15–16.
18. 456ᵇ5, *HA* 521ᵃ9–10, *PA* 647ᵇ4–7, 665ᵇ9–17, 666ᵃ5–11.
19. *HA* 494ᵃ4–ᵇ11, *PA* 3.4–5.

and the thicker blood into the lower places. And whenever this happens, once they have been released from the weight of the nourishment, animals wake up.

What the cause of sleeping is, then, has been stated,[20] namely, that it is the reciprocal replacement [of hot with cold material] due to the corporeal exhalation being carried upward by the innate heat acting all at once upon the primary perceptual organ; and it has also been stated what sleep is, namely, that it is a seizure of the primary perceptual organ that renders it incapable of being active, occurring of necessity (for it is not possible for an animal to exist if the things that bring it to completion do not come about), and is for the sake of preservation; for rest preserves.

20. 457[b]1–2.

ON DREAMS*

De Insomnis

1
To Which Part of the Soul Does Dreaming Belong?

Next we must inquire about the dream, and, first, to which of the parts of the soul it appears to belong, that is, whether this affection belongs to the understanding part or to the perceptual one; for it is only by way of these capacities in us that we know things. **458ᵇ1**

Since the use of sight is seeing, and that of hearing is hearing, and, in general, that of perception is perceiving, and since there are objects that are common to the perceptual modalities, such as shape, magnitude, and the others of this sort,[1] and since all animals are incapable of seeing when their eyes are closed and while asleep, and similarly also with the other perceptual modalities, it is clear that we do not perceive anything during sleep. Therefore, it is not with perception, at any rate, that we perceive dreams.

But neither is it with belief; for [in belief] we assert not only that the approaching thing is a human being or a horse but also that it is white or beautiful—things of which belief could not assert anything, either truly or falsely, without perception. But in sleep it happens that the soul does this, for [in a dream] we equally believe that we see that the approaching thing is a man and that it is white.

Further, alongside a dream we think something else, just as we do in waking when we perceive something. For often we also think something about what we are perceiving; and in this same way in sleep too we sometimes think other things alongside the [dream] appearances. This should become evident to anyone who directs his thought [to a dream] and tries to remember it on arising. In fact, some people have seen dreams of this sort—for example, those who [while dreaming] believe that they can arrange the things presented to them in accord with a mnemonic precept. For it happens to them that they put some other appearance in that place before their minds alongside the dream one. It is clear, then, that not every appearance in sleep is a dream, and that what we think is something we believe by the capacity of belief.

From all these considerations this much at least is clear, that the same [part] by which we are deceived when awake and sick is also the one that produces the affection during sleep. Even to those who are healthy and who know [that it is not the case]

* Translated by Klaus Corcilius. Text: As for *De Sensu*.

1. Accepting the seclusion of ἢ τὰ ἴδια οἷον χρῶμα ψόφος χυμός ("or the special objects such as color, sound, flavor").

the sun still seems to be a foot across. But whether the imaginative part of the soul is the same as, or distinct from, the perceptual part, nonetheless [dreaming] will not occur without seeing or perceiving something. For to mis-see or to mis-hear involves seeing and hearing something true, though it is not what the person thinks. But it is assumed that in sleep one neither sees, nor hears, nor perceives anything at all. Is it true, then, that one sees nothing, but not true that perception is not at all affected, and that instead it is possible that sight undergoes a certain affection, and also the other perceptual modalities, and that each of them somehow impinges on perception, just as when one is awake, but not in the same way as when one is awake? And sometimes the belief says that it is false, as in people who are awake, while at other times it is held back and follows along with the appearance.

That this affection we call "dreaming," then, does not belong either to the part that forms beliefs nor to the thinking part is evident. But nor does it belong simply to the perceptual part, for then it would simply be seeing or hearing. But how and in which way [it does so], then, must be investigated.

Let it be assumed, the precise thing that is also evident, that it is an affection of the perceptual part, if indeed sleep is too. For it is not the case that sleep belongs to one sort of animal and dreaming to another, rather, they belong to the same one. But since we have spoken about imagination in the *De Anima*,[2] and since the imaginative part is the same as the perceptual part, though the being for imagination and the being for perception are distinct, and since imagination is a movement occurring due to active perception, and since a dream seems to be a sort of appearance (for we call an appearance during sleep a "dream," either unconditionally or one that comes about in a certain way), it is evident that dreaming belongs to the perceptual part, but that it belongs to it insofar as it is imaginative.

2
The Subject of Dreaming

We will be best able to get a theoretical grasp on what a dream is, and how it comes about, from what happens in connection with it. For the perceptual objects corresponding to each perceptual organ produce perception in us, and the affection that results from them is present in the perceptual organs not only when the perceptual modalities are active, but also after the perceptual objects have gone away. In such cases the affection seems to be much the same as in the case of things in spatial movement. For in the case of things in spatial movement too, the movement continues even though there is no longer contact with what moved them; for the mover moved a certain portion of air, and this, since it was moved, in turn moved another portion; and in this way, then, movement in both air and in liquids is produced, until it comes

2. 3.3.

to a stop. Likewise, one must suppose this to be so in the case of alteration too. For **459^{b}1**
what is heated by something hot heats what is next to it, and this passes it on until
it reaches the starting-point. So it is necessary that this also happens in perceiving,
since active perception is a sort of alteration. That is why the affection is not only in
the perceptual organs while they are perceiving, but also when they have ceased to do
so, and this both deep inside and on the surface.[3]

This is evident whenever we perceive something continuously. For when we shift
our perception, for example, from the sun to darkness, the affection follows along
with it; for it then happens that we see nothing because of the movement due to the
light still subsisting in our eyes. And if we look at one color, whether white or green,
for a long time, whatever we turn our sight to next appears to be of that same color.
And if, after having looked into the sun or into some other bright object, we close
our eyes, if we watch closely, the object appears right in front of us wherever our
sight happens to look, at first in the same color, then it changes to crimson, next to
purple, until it comes to black and disappears. Also, to those who turn their eyes away
from moving things, such as rivers, and especially from those that flow fastest, the
things that are at rest appear to be moving. Again, people also become deaf from loud
sounds, and from strong odors they become bad at smelling similar objects. These
things manifestly take place in the way we say.

A sign that the perceptual organs quickly perceive even slight differences is what
happens in the case of [bronze] mirrors, which, even when attended to by itself, is
something one might investigate and raise puzzles about. At the same time, it is clear
from this that just as the organ of sight is affected it also produces an effect. For when
menstruating women look into the mirror, in the case of extremely clean mirrors, the
surface of the mirror becomes like a bloody cloud; and if the mirror is new, it is not
easy to remove this sort of stain, but if it is old, it is easier. The cause, as we said, is
that the organ of sight is not only affected by the air but also produces an effect and **460^{a}1**
causes movement, just as bright objects also do; for the organ of sight is a bright and
colored object too.

It makes good sense, then, that the eyes during menstruation are in a condition
just like any other part of the body; for by nature they are full of blood vessels. That
is why when menstruation occurs, due to the disturbance and bloody inflammation,
the resulting difference in the eyes is not clear to us, but is still present (for seed and
menstrual fluid have the same nature),[4] and the air is moved by them, and it makes
the air on the mirror, which is continuous with it, have a certain quality, that is, the
same one it itself is affected by, and the air does the same to the surface of the mirror.

Just as with garments, the cleanest mirrors are the quickest to get stained. For
what is clean shows exactly whatever it receives, and what is so to the highest degree
shows the smallest movements. But bronze, because it is smooth, best perceives any

3. *Somn.* 456^{a}20–21.
4. I.e., they are involved in the transmission of form, in the present case that of color.

contact (one must understand the contact of the air as a sort of friction and, as it were, a wiping and washing), and because it is clean, contact of whatever intensity is manifest. And cause due to which the stains do not easily go away from new mirrors is that they are clean and smooth. For the stain penetrates such things both in depth and all over; in depth because of the cleanness, all over because of the smoothness. But the stain does not remain on the old mirrors because it does not penetrate in the same way but is more superficial.

That movement is also produced due to slight differences, then, and that perception is quick, and that the perceptual organ of colors is not only affected, but also produces an effect in return, is evident from these considerations. Evidence for what has been said is provided by the things that happen with wine and in the manufacture of perfumes. For the oil, once prepared, quickly takes on the smell of the objects next to it, and the wine does too. For they take on not only the smells of what is thrown into them or mixed with them, but also those of the things that are placed next to the vessels that contain them, or that grow there.

But in relation to the question at the start let one thing be assumed, which is
460b1 precisely what is evident from what has been said, that even when the external perceptual object has gone the perceptual affections remain and are themselves perceptual objects; and in addition that we are easily deceived when we are in the grip of feelings, and distinct people in distinct ones—for example, the coward when in the grip of fear, and the lover when in the grip of love, so that from a slight similarity the one believes he see his enemies, and the other his beloved. And the more in the grip of a feeling he is, the smaller the similarity due to which things appear so. And in the same way all people become easy to deceive when in the grip of anger and all sorts of appetites, and the more so, the more they are in the grip of the feelings. That is also why to those in a fever sometimes animals appear on the walls due to a slight similarity in the composition of the lines there. And these appearances sometimes agree in intensity with the feelings in such a way that when they are not very ill it does not escape their notice that it is false, but when the affection is more severe, they even move themselves in connection with these.

The cause of these occurrences is that it is not in virtue of the same capacity that the controlling part judges and that the images come about. A sign of this is that the sun appears a foot across, but often something else speaks against the appearance. And when the fingers are crossed, one object [placed between them] appears to be two [to touch]; but we nonetheless deny that it is two; for another [perceptual modality] is more controlling than touch, namely, sight. But if there was only touch, we would also have judged the one object to be two. The cause of our being deceived is that things of any sort whatever appear not only when the object of perception causes movement, but also when perception itself is moved as if due to a perceptual object. I mean, for example, that the earth seems to be moving to those who sail, though their sight is moved by something else.

3
The Efficient Cause of Dreaming

From these considerations, then, it is evident that the movements from the perceptual affections, coming both from the outside and from the body itself, do not occur only in waking people, but also when this affection called "sleep" occurs, and then they even appear to occur more. For during daytime these movements are knocked out since the perceptual modalities and thought are active, and they vanish just as a smaller fire vanishes next to a big one and small pleasures and pains next to great ones, but when these stop, the small [movements] surface too. But at night—because of the idleness of the particular perceptual modalities and their incapacity to be active, due to the backflow of the heat from the external parts to the inner parts of the body—the movements are carried down to the starting-point of perception[5] and become apparent when the disturbance has settled.

We must suppose, then, that, just as little eddies are carried along in rivers, so each [such] movement occurs continuously, often remaining the same, but often dissolving into other shapes because of striking against something. That is why dreams do not occur after meals or to those who are altogether young, such as small children. For there is a great deal of movement due to the heat from the nourishment. So, just as in a liquid, if there is violent movement, sometimes no reflected image appears, while at other times it does appear, but is altogether distorted, so that it appears other than what it is, but once the movement has come to a rest, the reflected images are clear and evident, in this same way during sleep too the appearances—that is, the remaining movements that come about from the perceptual affections—sometimes, by a movement greater than the mentioned one, vanish altogether, while sometimes the visions appear confused and monstrous, and the dreams are incoherent as in impulsive people and in those who are feverish or drunk. For all affections of this sort, since they are breath-like, cause much movement and disturbance.

When the blood in blooded animals calms down and gets disaggregated, the movement from each of the perceptual affections, when preserved, makes the dreams coherent, and so something appears, and because of the movements that are carried down from the eyes [to the heart], the dreaming person believes he sees, and because of the movements [carried down] from the ear he believes he hears, and in a similar manner too with the movements from the other perceptual organs. For it is due to the movement arriving from there at the starting-point [of perception] that the waking person too believes that he sees and perceives, and sometimes we say we see because the organ of sight seems to be moved, even though it is not. Also, one thing seems to be two because touch reports two movements. For, in general, the starting-point affirms what comes from each perceptual modality, unless some other more controlling capacity speaks against it. And in every case there is something that

5. *Somn.* 456ᵃ4–6.

appears, but one does not believe what appears in every case, unless the judging one[6] is held back or is not moved with its own movement.

And in the way we said[7] that distinct people are easily deceived by distinct affections, so also the sleeping person, because of sleep, the movement of the perceptual organs, and the other things that happen regarding perception, so that something that has only a slight similarity to it appears to be the actual thing. For when one sleeps, since most of the blood moves downward toward the starting-point, the movements that are present in it, some potential and some others active, move down with it. The movements are so related that if anything moves the blood, this movement will rise to the surface from it, and when this one passes away, another [will too]. And they are related to each other just like the fabricated frogs[8] that come up in water as the salt melts. This is the way they are potentially present [in the blood], and they become active when the hindrance has slackened, and, on being let loose in the little remaining blood that is moved in the perceptual organs, they bear resemblances just like clouds do, which people liken to human beings and to Centaurs as they rapidly change.

Each of these, as was said,[9] is a remnant of the active perceptual affection. And they are present even when the true one has gone away, and it is true to say that this is like Coriscus but is not Coriscus. And when it was perceiving, the controlling and judging capacity did not say that [the affection] is Coriscus, but rather it said because of it that that true one is Coriscus. The same capacity, then, with which one says this during perception, unless it is entirely held back by the blood, is now moved by the movements in the perceptual organs as if it was perceiving, and what is similar [to a thing] seems to be the actual thing itself. And the capacity of sleep is such as to make this escape one's notice.

Hence, it is just like if someone is unaware that a finger is been pressed under his eyeball,[10] it will not only appear to him, but he will also believe, that what is one thing is two, while when he is not unaware of this, it will appear so to him, but he will not believe it. So too during sleep, when someone perceives that he sleeps (that is, he perceives the affection in which the perceptual capacity of the sleeper finds itself), something appears to him, but something in him says that though it appears to be Coriscus, it is not Coriscus (for often during sleep something in the soul says that what appears is a dream); but when he is unaware that he sleeps, nothing will speak against the appearance.

That we are speaking the truth and that there are movements capable of producing appearances in the perceptual organs is clear, if one directs one's attention to

6. 460ᵇ16–18.
7. 460ᵇ3–7.
8. These were evidently stacked on top of each other and so weighed down with a covering of salt that one surfaced after another.
9. 460ᵇ2–3.
10. *Met.* 1063ᵃ6–10.

it and tries to remember how we are affected when we fall into sleep and when we wake up. For sometimes, in the moment of awakening, one will discover the images that appear during sleep as being movements in the perceptual organs. For to some younger people, even when they open their eyes altogether wide during darkness, there appear many moving images, so that they often cover up their heads in fear.

From all these considerations, then, one must deduce that a dream is a sort of image and that it occurs during sleep. For the appearances just mentioned are not dreams, nor is anything else that appears while the perceptual modalities are released [from sleep]; nor is every appearance in sleep a dream. For, first, it happens to some people that they somehow perceive sounds, light, flavor, and touch, but weakly and as if from afar. For in fact there have been people that blink while they sleep who dimly saw the light of a lamp during sleep, as they thought, and immediately after waking recognized it as the light of the real lamp, and also those that have dimly heard the voice of cocks and dogs that they recognized perspicuously upon awaking. Some people even reply to questions put to them [while they are asleep]. For it is possible in the case of waking and sleeping that, while one of them is present unconditionally, the other be present in a way. None of these must be said to be a dream, nor must any of the true things understood that occur in sleep alongside the appearances,[11] but rather the appearance due to the movement from the perceptual affections, when it occurs during sleep, and insofar as one is sleeping—this is a dream.

But cases have been observed of people who have never seen a dream in their whole lives, while others have seen a dream only at an advanced age having never dreamed before.[12] The cause of their not having dreams appears to be much the same as the case of young children and what happens after meals.[13] For it is reasonable that no appearance appears to all those whose nature is composed in such a way as to have much exhalation moving upward to the upper place, which, when it descends, produces a great quantity of movement. But with older age it is not at all strange if a dream appears to them. For when a change has taken place either in virtue of age or in virtue of an affection, this contrary condition necessarily results.

ON PROPHECY DURING SLEEP*

De Divinatione per Somnum

1
Is Prophecy during Sleep Possible?

As regards the prophecy that occurs during sleep and that is said to come about from dreams, neither to despise it nor to be persuaded by it is easy. For the fact that all or many people suppose that dreams have something significant about them is a persuasive factor, since it is something said on the basis of experience; also, that in some cases there is prophecy in dreams is not unpersuasive; for there is some reason for it. That is also why one might think in a similar way about the other dreams too. On the other hand, to see no reasonable cause due to which it might come about, makes one not be persuaded. For to hold both that the god is the one who sends [prophetic dreams], and that he sends them not to the best and wisest people but to random ones, is—in addition to its other inconsistencies—absurd. But once causation from the god has been excluded, none of the other causes seems reasonable either. For it would seem beyond our comprehension to discover the starting-point from which some people foresee events at the Pillars of Heracles or on the banks of the Borysthenes.

Necessarily, then, dreams are either causes or signs of events, or else they are coincidental concomitants, and they are either all or some of these, or only one. By "cause" I mean, for example, as the moon is of the eclipse of the sun, and fatigue of the fever; by "sign" as the entrance of a star[1] into the shadow is of the eclipse, and as the roughness of the tongue is of the fever; and by "coincidental concomitant" that someone is walking when the sun is eclipsed; for this is neither a sign of the eclipse nor a cause, and neither is the eclipse of the walking. That is why none of the coincidental concomitants occurs always or for the most part. **463ª1**

Is it, then, that some of the dreams are causes and signs, as for example of the things that occur in the body? At any rate, even the more sophisticated of the doctors[2] say that one must pay attention to dreams. And it is reasonable for those who, though not practitioners of the craft, are investigating [the issue] and philosophizing about it, to suppose so as well. For the movements that occur during daytime, unless they are very great and strong, escape notice alongside the larger waking movements. During sleep the opposite is the case, however, for even the small movements seem to be

* Translated by Klaus Corcilius. Text: As for *De Sensu*.

1. Probably the appearance of a star when the sky is darkened by a solar eclipse.

2. *Sens.* 436ª19–ᵇ1, *Juv.* 480ᵇ26–30.

great. This is clear in the case of what often happens during sleep. For then people think that there is thunder and lightning while there are faint sounds in their ears, that they are enjoying honey and sweet flavors when a droplet of phlegm runs down their throat, or that they are walking through fire and feeling intense heat when there is a slight heating in some parts of their bodies. But once they are awake, it is evident the way things are. So, since the starting-points of all things are small, it is clear that this holds also for illnesses and other affections that are about to occur in the body. It is evident, then, that these things are necessarily more manifest during sleep than during waking.

Moreover, it is not unreasonable that at least some of the appearances that occur during sleep are causes of the actions corresponding to each of them. For, just as when we are about to act, or are engaged in doing actions, or have already done them, often, in a vivid dream, we find ourselves concerned with these actions and even performing them, in that same way it is conversely necessary that the movements that occur during sleep are also often starting-points of our daytime actions, because our thinking has conversely paved their way in the appearances that occurred during the night. In this way, then, it is possible that some dreams be both signs and causes.

However, many dreams seem most of all like coincidental concomitants, and in
463b1 particular all the extravagant ones, that is, those whose starting-point is not in the dreamers themselves, but instead are about a naval battle and things that happen far away. For regarding these dreams, it is likely that the same thing happens as in the case of those who have remembered something, and this very thing comes to pass. For what prevents this from happening in dreams as well? Rather, it is likely that many things of that sort happen. Just as remembering this person, then, is neither a sign nor a cause of his presence, so also in this case the fact that the thing happens after the dream is for the person who saw it neither a sign nor a cause, but a coincidental concomitant. That is why many dreams do not become true. For coincidental concomitants do not occur either always or for the most part.

2
The Explanations

In general, though, since some of the other animals dream as well, dreams would not seem to be sent by a god, nor do they occur for that purpose; they are, however, daimonic, for nature is daimonic, but not divine.[3] There is a sign of this, for completely worthless people are capable of foresight and of dreaming vivid dreams, implying that it is not a god that sends them; but rather that people with a garrulous and impulsive sort of nature see visions of all sorts; for they, because they undergo many movements in all sorts of ways, chance to have visions similar to actual events since they are lucky

3. *Somn.* 453b20–24.

in this, just like some people who play at odd or even; for, as the saying goes, "if you make many throws your luck must change," which holds in their case as well.

That many dreams do not come true is nothing strange. For it is also not the case that many signs in the body or in the sky, such as those of rains or winds (but still if another movement occurs that has more control than this one due to which it was a sign of a future event, the event does not occur), and many of things that should be done, even though deliberated about correctly, are canceled because of other more controlling starting-points. For, in general, not everything that was going to happen occurs, nor is what will be the same as what is going to happen;[4] but still it must be said that some of these are starting-points due to which nothing was accomplished, and these are natural signs of events that did not occur.

But as regards the dreams we have spoken of[5] that have no such starting-points but are outlandish in time, in place, or in magnitude, or that are outlandish in none **464^{a}1** of these ways, yet do not have their starting-points in the people themselves who see the dream, provided their foreseeing does not happen due to a coincidental concomitance, the following would be better than to say, as Democritus[6] does, that images and effluences are the causes. For just as when something causes movement in water or air, this causes movement in something else, and when the first cause has ceased, it happens that a similar movement continues up to a certain point, even though the first mover is not present, in this same way nothing prevents a certain movement and perception from arriving at dreaming souls (coming from the things Democritus makes the images and effluences come from); and wherever they happen to arrive, they are more perceptible at night because movements that are carried along during daytime are more liable to dissolution (for the air is less disturbed at night because nights are less windy), and they produce perception in the body because of sleep, because sleeping people perceive even small internal movements more than those who are awake. And these movements produce appearances, from which people foresee what is going to happen even as regards things of this sort.[7]

That is also why this affection occurs to random people and not to the wisest ones. For during daytime it would also occur in the wise ones, if a god was the sender. But in this way[8] it is reasonable that random people have foresight. For the thought of these people is not busy with thoughts but rather, as it were, deserted and empty of all things, and once moved it darts in accord with what moves it. The cause of some excitable people's having foresight is that their own movements do not disturb but rather pave the way [for the incoming movements]; hence they especially perceive alien movements.

4. *GC* 337^{b}4–7.
5. 463^{a}31–^{b}11.
6. A77 DK.
7. I.e., outlandish ones.
8. I.e., as it has just been explained.

That some people have vivid dreams, for example, that people who know each other have foresight especially with respect to the ones they know, happens because people who know each other care about each other most. For just as they very quickly
30 know and perceive each other from far away, so they also perceive each other's movements; for the movements of the ones they know are more familiar. And impulsive people, because of their vehemence, as if they were throwing from afar, are good at hitting the mark, and because of their changeability, what comes next appears to
464b1 them quickly. For just as even mad people recite and think in their minds the poems of Philaigis, which are connected by similarity like "Aphrodite" and "phrodite," in this same way also impulsive people go on stringing things together. Further, due to their vehemence their movements are not knocked out by other movements.

5 The most craftsman-like judge of dreams is the one capable of observing resemblances (for anybody can judge vivid dreams). I say "resemblances," because what happens in the case of appearances is much the same as happens to images in water, as
10 we also said previously.[9] But there, when the movement becomes great, the reflection and the images bear no resemblance at all to the real objects. Truly clever at judging the appearances would be the person capable of quickly and distinctly perceiving and immediately comprehending the scattered and distorted fragments of these images, namely, that it is the reflection of a human being, or of a horse, or of whatever else—
15 it is the same, then, in the case of seeing what this dream means; for the internal movement knocks out the vividness of the dream.

What sleep is, then, and what dreaming is, and due to what cause each of them comes about, and, further, about all the prophecy that comes from dreams has been stated.

9. *Insomn*. 461a14–25.

ON LENGTH AND SHORTNESS OF LIFE*

De Longitudine et Brevitate Vitae

1
Puzzles about Longevity

As regards the fact that some animals are long-lived, others short-lived, and as regards length and shortness of life in general, the causes must be investigated. And the necessary starting-point of this investigation is to go first through the puzzles about these things. For it is not evident whether the cause of some being long-lived, others short-lived, is a distinct one or the same for all animals and plants. For some plants too last [only] one year while others live longer. A further puzzle is whether among the things that are naturally composed the same ones are long-lived and healthy in their nature, or whether being short-lived and being sick are separate [affections], or for some illnesses the bodies that are ill in their nature coincide with those that are short-lived, while in other cases nothing prevents those that suffer from an illness from being long-lived.

Sleep and waking were spoken about previously, and life and death must be spoken about later, and likewise illness and health, to the extent that they pertain to natural philosophy; now, though, we must get a theoretical grasp on the causes of some things being long-lived, others short-lived, as was said previously.[1] Whole **465ª1**
kinds have this difference with respect to whole kinds, and also individuals that fall under one form differ from one another [in this way]. By "different according to kind" I mean the human being with respect to the horse (for human beings as a kind live longer than horses), and [by "different] according to form," a human being with respect to another human being. For some human beings are long-lived, others short-lived, because they are set apart by the distinct places in which they live. The nations who live in hot places are longer-lived, while those who live in cold places are shorter-lived. Even among those who live in the same place, some are different in a similar way with respect to this difference from each other.

* Translated by Andrea Falcon. Text: W. D. Ross, *Aristotle: Parva Naturalia* (Oxford, 1955).

1. 465ª19–20. The order of treatises suggested is *Somn.* (including *Insomn.* and *Div. Somn.*), *Long., Juv*. A study of the starting-points of health and illness is announced also in *Sens.* 1 but nothing by Aristotle on it survives.

2
Modes of Destruction

One must grasp, then, what it is in naturally constituted things that makes them easy to destroy, and what it is that makes them not easy to destroy. For fire, water, and the things that are akin to them, although they do not have the same capacity, are the cause of coming to be and passing away for each other, so that it is reasonable that all the other things that come from these and are composed out of them partake of their nature, except for those that, like a house, are a combination of many things.

As regards the other things, then, there is a different account; for there are modes of passing away that are special to many beings—for example, to scientific knowledge and ignorance, health and disease. These things pass away even if the things that are receptive of them do not pass away but are instead preserved—for example, recollection and learning are a passing away of ignorance, and forgetting and error of scientific knowledge. But the passing away of these other things follows coincidentally on the passing away of the natural ones; for when animals pass away, the scientific knowledge and health in the animals also pass away. That is why, as regards the soul too, one might draw a conclusion; for if it is not by nature but rather in just the way scientific knowledge is in a soul that the soul is likewise in a body, there should be another mode of passing away that is special to the soul beyond the passing away that it undergoes when the body passes away. So, since there is manifestly no such mode, the soul must have its communion with the body in a different way.

3
A Puzzle

465b1 But perhaps someone might reasonably raise a puzzle as to whether there is a place where what admits of passing away becomes incapable of passing away, as fire does in the upper place where there is no contrary. For what belongs to contraries coincidentally passes away because the contraries pass away; for contraries do away with each other. But none of the contraries that are in substances passes away coincidentally because a substance is not predicated of any subject.[2] So it would be impossible for what has no contrary, or is in a place where there is none, to pass away. For what will be the cause of its passing away, if indeed its passing away only comes about due to contraries, while a contrary either does not exist altogether or does not exist in that place?

Or is this true in one way and not true in another? For it is impossible for a contrary not to belong in some way to what has matter.[3] For it is possible for the hot

2. *Cat.* 5.
3. I.e., not to belong potentially to what has matter.

or the straight to be present in every thing, but it is impossible for the whole thing to be either hot or straight or white; for then the affections would be separate. If, then, what can affect and what can be affected are simultaneous, it is always the case that one affects and the other is affected, and it is impossible for there to be no change. Further, [this is so] even if it is necessary for a residue to be produced, and the residue is a contrary; for change is always from a contrary, and the residue is a leftover of the previous contrary.

But if what is actively a contrary is driven out as a whole, would at that point the thing become incapable of passing away? Or is this not so, but rather the thing would pass away due to the environment? If it is, then what has been said is enough; but if it is not, it must be assumed that something that is actively a contrary is present and that a residue is produced. That is why a smaller flame is accidentally burned up by a greater one, because the nourishment that the smaller flame uses up in a greater time, which is the smoke, the greater flame uses up quickly.[4] That is [also] why everything is always in movement, that is, coming to be or passing away. The environment, for its part, acts either in a co-operative or in an opposite way, and because of this the things that change their place come to be longer-lived or shorter-lived than their nature warrants, but they—[at any rate] those in which there are contraries—are never eternal. For their matter involves contrariety from the outset, so that if it is of place, the thing changes with respect to place; if of quantity, the thing changes with respect to growth and decay; and if of affection,[5] the thing undergoes alteration.

4
Failed Correlations and Trans-generic Facts

The animals that are less capable of passing away are neither the largest ones (for the horse is shorter-lived than the human being) nor the small ones (for many insects live for [only] one year); nor are plants in general less capable of passing away than animals (for a few plants live for [only] one year); nor are blooded animals (for bees live longer than a few blooded animals); nor are the bloodless animals (for the soft-bodied animals, though they live for [only] one year, are bloodless) nor are the terrestrial ones (for there are plants and terrestrial animals that live for [only] a year); nor the ones that live in the sea (for in that place both the hard-shelled animals and the soft-bodied ones are short-lived).

In general, the longest-lived ones are found among plants—for example, the date palm. Next, among blooded more than the bloodless animals, and among the terrestrial animals more than the aquatic animals. As a result, when those two features are combined, the longest-lived animals are found among the blooded terrestrial

4. Retaining διὸ . . . ταχύ.
5. I.e., quality.

animals—for example, the human being and the elephant. And, indeed, the largest animals live for the most part longer than the smaller animals; for the other longest-lived ones also happen to be of large size, as in the case of those mentioned.

5
Length and Shortness of Life in Animals Explained

As regards all the above facts, one should get a theoretical grasp on the cause starting from what follows. For it must be grasped that the animal is by nature wet and hot, and to be alive is such, while old age is dry and cold, and so is what is dead; for this is manifestly so. These things—the wet and the hot, the dry and the cold—are the matter for the bodies of animals. It is therefore necessary that as animals age they become dry. That is why the wet must not be easy to dry up. And because of this, oily things are incapable of putrefying. The cause is that they are made of air, and air is fire in relation to the other [elements], and fire never becomes putrefied. Again, the liquid must not be small in quantity; for what is small in quantity is also easy to dry up. That is why the largest ones, both animals and plants, are, to speak in general terms, longer-lived, as was said previously;[6] for it is reasonable for the larger creatures to contain more liquid.

But it is not only because of this that they are longer-lived; for there are two causes, the quantity and the quality, so that the wet must not only be great in quantity, but also be hot in order to be neither easy to solidify nor easy to dry up. And because of this the human being is longer-lived than some of the large animals; for the animals that are deficient in the quantity of liquid are longer-lived if the quality
466b1 of their liquid proportionally exceeds its deficiency in quantity. And in some animals the hot is the oily, which at the same time makes something neither easy to dry up nor easy to solidify. And in some animals it has a different flavor.[7]

Further, what is not to be prone to passing away must not be productive of abundant residue; for something of this sort is destroyed either by disease or by nature; for the capacity of residue is contrary and destructive—sometimes of the [animal's] nature and sometimes of a part [of it]. That is why animals that mate frequently and animals that have abundant seed grow old quickly; for seed is a residue and, further, dries [the body] when it leaves. And because of this the mule is longer-lived than both the horse and the ass from which it came to be, and females than males when the males mate frequently; that is why the male sparrows are shorter-lived than the females. Further, males that are more accustomed to hard labor are also [shorter-lived] and, because of the hard labor, grow older more [quickly]; for the hard labor dries [the body], and old age is dry. By nature, and to speak in general about all

6. 466a9–16.
7. *Sens.* 442a17–19.

cases, males are longer-lived than females; the cause is that the male is a hotter animal than the female.

The same animals are longer-lived in sunny than in cold places due to the same cause due to which they are also larger. And above all the size of the animals that are in their nature cold makes this clear. That is why snakes, lizards, and animals with scales are large in hot places, and the hard-shelled animals in the Red Sea; for the warm liquid is the cause of their growth and life. But in cold places the liquid that is present in the animals is more watery. That is why it is easier to solidify, so that some of the animals that have little blood or are bloodless do not occur at all in northern places (neither terrestrial animals on land nor marine animals in the sea), while others occur but are smaller and shorter-lived; for the frost takes away from their growth.

Both plants and animals pass away if they do not take in nourishment; for they consume themselves. For just as the large flame burns up and destroys the small one by using up its nourishment, so the natural heat, which is what is the first responsible for concoction, uses up the matter in which it is present.

The aquatic animals are less long-lived than the terrestrial animals, not because they are simply wet, but because they are watery. And this sort of liquid is easy to destroy because it is cold and easy to solidify. And what is bloodless [is easy to destroy] due to the same cause whenever it is not protected by its size; for it is neither oily nor sweet; for in the animal, the oily is sweet. That is why bees are longer-lived than other larger animals.

6
Relative Length and Shortness of Life in Animals and Plants Explained

The longest-lived beings are found among plants, and more among plants than among animals, first because plants are less watery, so they are not easy to solidify. Further, they have oiliness and viscosity, which is why, even though they are dry and earthy, the liquid they have is nonetheless not easy to dry up.

But as regards the nature of the trees, the cause must be grasped as to why they live longer; for they have a nature special to them in relation to the animals, except in relation to insects. For plants renew themselves continuously, which is why they live a long time. For there are always other shoots while the old ones grow old, and the roots are the same way, although not at the same time. Rather, at one time the trunk and the branches alone die, and new ones grow up next to them. Whenever they do so, other roots spring from the existing part of the plant, which in this way continues to live while being in one way destroyed and in another growing. That is why [trees] are long-lived.

Plants are like insects, as was said previously;[8] for when they are cut, they stay alive, and become two or more from one. But the [resulting] insects, though they manage to stay alive, cannot do so for long; for they do not have instrumental parts,[9] and the starting-point of life that is present in each [section] cannot produce them. But the starting-point present in the plants can; for plants have a root and a stem everywhere potentially. That is why it is from this starting-point that what is new and what is getting old [in the plant] continually emerge, and there is little difference between this sort of longevity and propagation by taking cuttings.[10] For one might claim that the same also happens, in a certain way, in the case of propagation by taking cuttings; for what is cut off is a certain part. Thus, in the case of propagation by taking cuttings this happens when the cutting is separated from the plant, while in the case of the plant, it is because of its being conjoined with it. The cause is that the starting-point of life is present potentially in every part.

The same thing occurs in both animals and plants. For in animals the males are for the most part longer-lived—their upper parts being larger than the lower parts (for the male is more dwarf-like than the female). And the hot is in the upper part and the cold in the lower. In plants too those with a weighty head are longer-lived. Those that do not live for one year but are tree-like are of this sort. For the upper part of the plant and its head are the roots,[11] and the plants that live for one year take their growth in the direction of the lower parts and the fruit.

About these matters by themselves determinations will be made in the work concerning plants.[12] Now, though, the cause of length and shortness of life has been given for animals as well.[13] It remains for us to get a theoretical grasp on youth and old age, life and death. Once these things are determined, the methodical inquiry concerning the animals will come to an end.

ON YOUTH AND OLD AGE, LIFE AND DEATH, AND BREATHING*

De Juventute et Senectute, de Vita et Morte, de Respiratione

1
The Nutritive and the Perceptual Soul and Their Relation to the Body

Youth and old age, as well as life and death, must now be spoken about; at the same time the causes of breathing must presumably be stated; for it is because of this that some animals are either living or not living.

Since determinations about the soul were made elsewhere, and it is clear that the substance of the soul cannot be a body,[1] yet it is nonetheless evident that it must be present in some part of the body, and in one of those that have power over the others. Let us now, then, leave aside the other parts or capacities of the soul (whichever they should be called). But for all the things said to be animals and to be alive, among those that happen to be both (by "both" I mean both an animal and alive), there must be one and the same part in virtue of which the living being is alive and in virtue of which we call it an "animal." For it is impossible for an animal, insofar as it is an animal, not to be alive. But insofar as it is alive, it need not be an animal: for plants are alive, but they do not have perception, and it is by perception that we distinguish an animal from what is not an animal. It is necessary, then, for that part to be one and the same in number but more than one and distinct in being; for it is not the same thing to be an animal and to be alive.

Since, then, there is a single perceptual organ common to all the special perceptual organs into which the actual perceptions must come together, and this is located midway between what is called "front" and "back" (the part toward which perception comes to us is said to be the front, its opposite the back) and, further, since the body of all living things is divided into an upper and a lower part (for all living beings have the up and the down, including plants too), it is clear that the nutritive starting-point is to be found midway between them. For the part in virtue of which the nourishment comes in we call "up," looking at this part rather than its whole environment, while we call "down" the part in virtue of which the residue is first expelled. This **468ª1**

* Translated by Andrea Falcon. Text: W. D. Ross, *Aristotle: Parva Naturalia* (Oxford, 1955). In a few editions 470ᵇ5–480ª30 is printed as a separate treatise on breathing: that is why the chapters have double numbers. There is no evidence for this division in the manuscript tradition, and there is no ancient support for it. The treatise as a whole is a single textual unit.
1. *DA* 2.1–2.

is arranged in a contrary way in plants and animals. For among the animals, this arrangement is present above all in the human being because of its upright posture, that is, its having the upper part aligned with the up of the universe, while in the non-human animals the upper part is aligned with the middle region. But in plants, because they are immobile and get their nourishment from the earth, this part must always be down; for the roots in plants are an analog to what is called a "mouth" in animals. Both animals and plants get their nourishment through this part: the plants from the earth, and the animals by their own efforts.

2
The Central Location of the Nutritive and the Perceptual Soul

There are three parts into which all complete animals are divided: one by which the nourishment is received, one by which the residue is expelled, and the third is midway between them. And this last is called the "chest" in the largest animals, while in the other animals it is the analog, and it is more articulated in some animals than others. And in all those capable of moving by progression, there are additional parts attached for this very task, by which they carry the whole trunk: legs as well as feet and those parts that have the same capacity as these. But, at any rate, the starting-point of the nutritive soul is in the middle one of these three parts, as is evident both according to perception as well as according to argument.

For in the case of many animals, when either of the parts is removed, that is, the part that is called "head" and the part that receives the nourishment, they continue to live by aid of that part which is joined with the middle one. This clearly happens in the case of insects, such as wasps and bees; and many animals that are not insects are able to live when divided due to their nutritive part. A part of this sort is actively one, but potentially more than one. For these animals are composed in the same way as plants; for plants too, when divided, continue to live separately, and many trees come to be from a single starting-point. The cause due to which some plants cannot continue to live when divided, while other plants propagate from cuttings, will be
468b1 the object of another account. But this holds in the same way both for plants and for the insect kind.

It is necessary, then, for the nutritive soul to be actually one but potentially more than one in those animals that have it. Likewise also for the perceptual soul; for it is evident that the divided parts of the animals have perception. But when it comes to the preservation of their nature, plants can preserve it, while these animals cannot, because they do not have the instrumental parts for preservation, with some lacking the part for taking in the nourishment, others the part for receiving it, and still others both of them and other parts as well. Animals of this sort are like many animals that have grown together. But those that are composed in the best way cannot be affected in this way because their nature is as unified as possible. That is also why some parts

produce a slight perception when divided, because they still retain some affection of the soul; for when the viscera are taken out, [the animal] still makes a movement, as do tortoises even when their heart has been removed.

3
Additional Arguments for the Central Location of the Nutritive and the Perceptual Soul

Further, it is clear [that the soul is located in the middle] in plants as well as in animals. In plants it is clear to those who investigate their generation from seeds, propagation by grafting, and propagation by taking cuttings.[2] For the generation from seeds occurs in all plants from the middle (for all seeds are bivalves,[3] insofar as they are grown together, and midway between each of the two parts is where both the stem and the root come out in growing plants, and their starting-point is the middle). In propagation by grafting and by taking cuttings this occurs above all around knots. For the knot is a kind of starting-point of the shoot, and at the same time it is also a middle, so that they either cut it off or graft into it in order that the shoot or the roots may come to be from it, on the supposition that the starting-point of the shoot and the root is from the middle.

And in blooded animals the heart comes to be first. This is clear from those cases that we have observed in which animals can be seen as they are still developing. As a result, it is necessary in bloodless animals too for the analog of the heart to develop first. And it was stated previously in the *Parts of Animals*[4] that the heart is the starting-point of the blood vessels,[5] and that blood, in blooded animals, is the nourishment at the final stage, from which [all] the parts develop. Therefore, it is evident, with respect to nourishment, that the mouth has the capacity to perform one sort of work, the stomach another, and that the heart is the most controlling part and adds the end. So it is necessary for the starting-point of the perceptual as well as of the nutritive soul to be in the heart in the case of blooded animals. For the work of the other parts concerned with nourishment is for sake of the work of the heart; for the controlling part should accomplish the for-the-sake-of-which—like a doctor in relation to health—rather than the things that are for the sake of this.

But what rules the perceptual modalities is surely located in the heart in all blooded animals; for in it the perceptual organ common to all perceptual organs must be located. And we see that two perceptual modalities—taste and touch—manifestly extend to the heart, so that it is necessary for the others to do so too; for

2. *Long*. 467ᵃ26–30, *GA* 761ᵇ26–29.
3. *HA* 528ᵃ12–13.
4. 665ᵇ10–22, 668ᵃ27–ᵇ3.
5. Reading ἀρχὴ τῶν φλεβῶν.

it is possible for the other perceptual organs to produce movement in this part, but taste and touch do not extend at all to the upper place.

Apart from these considerations, if being alive lies in this part for all animals, it is evident that the starting-point of perception must do so as well. For it is insofar as it is an animal that we also say that this one is alive; and it is insofar as it has the perceptual capacity that we say that the body is an animal. Why some of the perceptual modalities manifestly extend to the heart while others are located in the head (which is also why it seems to some that animals perceive because of the brain), the cause of this has been stated separately elsewhere.[6]

4
Additional Considerations for the Central Location of the Soul

According to the things that appear to be so, then, it is clear from what has been said that it is in middle part of the three parts of the body that the starting-point of the perceptual soul, as well as that of the soul involved in growth and nutrition, is located. According to argument, on the other hand, we see that in every case nature produces the best of what is possible. And when the starting-point is located in the middle of the substance, each of the two parts will most of all complete its own work, both the part that works on the nourishment at its last stage and the one that is receptive of it; for then the starting-point is situated in the same way with respect to both, and the central region of this sort is the region of what rules.

469[b]1 Further, what uses an instrument and the instrument it uses must be different (and just as in capacity so, whenever possible, also in place), just like pipes and what plays pipes, namely, the hand. If indeed, then, the animal is defined by having the perceptual soul, then blooded animals must have this starting-point in the heart, while bloodless animals in the analogous part.[7]

5
Vital Heat and the Ways in Which It Is Destroyed

All parts of the animals, as well as their entire body, have some innate natural heat. That is why they are manifestly hot while alive, and when they are dead and deprived of life they are manifestly in the contrary condition. It is necessary, then, for the starting-point of this heat to be in the heart in blooded animals, and in the analog in bloodless animals. For all the parts work on—that is, concoct—their nourishment by means of the natural heat, and the most controlling part does so most of all. That is

6. *PA* 656[a]15–657[a]11.
7. Beginning Chapter 5 here rather than at 469[b]21.

why, even when the other parts become cold, life remains [in the animal]. But when it happens in this part, life is destroyed altogether; for the starting-point of the heat for all the other parts comes from there, and the soul has been set aglow, as it were, in these parts—in the analogous part in bloodless animals and in the heart in blooded ones. Therefore, it is necessary for the presence of life and for the preservation of this heat to occur at the same time, and what is called "death" is its destruction.

But we see two ways in which fire is destroyed: exhaustion and extinction. We call "exhaustion" the destruction of fire caused by itself and "extinction" the one caused by its contraries. The first is due to aging, while the second is violent.[8] But it happens that both sorts of destruction come about due to the same cause; for when nourishment is lacking and when the heat cannot take in nourishment, fire is destroyed. [In extinction,] what is contrary, by stopping concoction, prevents fire from being nourished. But it is exhaustion that takes place when a great quantity of heat is amassed due to not breathing or cooling. For in this way too the great quantity of heat amassed quickly uses up the nourishment and gets at using it up before exhalation is established. That is why not only a smaller fire is exhausted when next to a larger one, but also the flame of a lamp burns out by itself when it is placed in a greater flame, just like any other combustible thing. The cause is that the larger flame, by seizing the nourishment in **470ª1** the [smaller] flame, destroys it before fresh nourishment comes in, while the fire is always becoming and flowing like a river, but so quickly as to escape notice.

It is clear, therefore, that if indeed the heat is to be preserved (and this is necessary if one is going to be alive), there must be some cooling of the heat in the starting-point. One may take as an example what happens to coals when they are damped down; for when they are covered all over continuously by what is called a "damper," they are extinguished quickly. But when one lifts the damper and puts it on again, alternating this quickly enough, they remain on fire for a long time. And banking up the fire preserves it; for it is not prevented from breathing owing to the porousness of the ashes, and it is protected by the surrounding air from being extinguished due to the great quantity of heat present in it. But this cause, why contrary outcomes result by banking the fire and damping it (the latter exhausts the fire, while the former preserves it for a long time), this has been spoken about in the *Problems*.[9]

6
Vital Heat and the Need for Its Regulation in Plants and Animals

Since everything that is alive has a soul, and this is not present without natural heat, as we said,[10] in plants the aid provided through their nourishment and the surrounding air is enough for the preservation of their heat. For in fact their nourishment, when

8. Retaining τὴν μὲν γήρᾳ, τὴν δὲ βίαιον.
9. Not in the extant *Problems* attributed to Aristotle.
10. 469ᵇ6–9.

it enters, makes them cool down (just as it does in human beings when they first consume nourishment), but fasting heats them up and makes them thirsty. For when the air is unmoved, it always becomes hot; but when nourishment comes in, the air is moved and cools[11] them until concoction is achieved. But when the environment is excessively cold due to the time of the year, if there are severe frosts, the strength of the heat fades away; but if there are spells of scorching heat and the moisture drawn from the soil is not enough to cool the plants, their heat is destroyed by exhaustion, and trees are said to be blighted and sun-scorched around such times. That is why they place certain kinds of stones and water in pots under the roots, in order for the roots of the plants to be cooled.

But when it comes to animals, since some live in water while others pass their time in the air, they procure their own cooling from these media and through them, the former ones by means of water, the latter by means of the air. In which way and how they do so must be stated after giving more attention to their account.

7 (1)
A Few Facts about Breathing

About breathing [only] a few of the early natural scientists have spoken. For the sake of which end breathing is present in animals, however, some have nothing to say, while others have spoken about it, but they have not done so well, but in a way that betrays inexperience of the relevant facts. Further, they say that all animals breathe, but this is not true. So it is first necessary to review the relevant facts so as not to seem to make empty accusations against those who are gone.

It is evident that all animals that have a lung breathe. But it is also evident that all those that have a [nearly] bloodless and spongy lung have less need of breathing. That is why they can stay under water for a long time relative to the strength of their body. And all egg-laying animals have a spongy lung—for example, the frog kind. Further, freshwater turtles and turtles can stay for a long time immersed in water, for their lung has little heat (for it has little blood). Once the lung is inflated, then, it cools the animal by its movement and enables it to stay [under the water] for a long time. However, if one forces these animals down under water for too long, they all suffocate; for no animal of this sort takes in water like fish do. The animals with a blooded lung have a greater need of breathing due to their greater amount of heat. But none of the others that have no lung breathes at all.

11. Reading καταψύχει.

8 (2)
Democritus, Anaxagoras, and Diogenes of Apollonia on Breathing (1)

Democritus of Abdera and some others who have spoken about breathing have made no determinations about the other animals but seem to speak as if all animals breathed. But Anaxagoras and Diogenes, claiming that all animals breathe, describe the way in which fish and oysters do so. Anaxagoras says that when they discharge water through their gills, fish breathe by drawing in the air that comes to be in their mouth; for he claims that there is no void at all. Diogenes says that when they **471ᵃ1** discharge water through their gills, they draw in the air from the water surrounding their mouth by means of the void created in the mouth, on the assumption that there is air in the water.

But these claims are impossible. For in the first place, they leave out half of the thing at issue because they speak only about what is common to both halves of it. For of what is called "breathing," one half is inhalation and the other half is exhalation. About this—the way in which such animals exhale—they have nothing to say. Nor can they say anything. For when fish have breathed, they must exhale again by that same route by which they inhale, and they must do this always in alternation, so that they at the same time take in water by the mouth and exhale air. But, since they meet, one must impede the other. Then, when they discharge the water, at that point they [also] exhale from their gills or from their mouth, with the result that they exhale and inhale at the same time; for they say that it is then that the animal breathes. But inhaling and exhaling at the same time is impossible. As a result, if the animals that breathe must exhale and inhale, and none of these animals can exhale, it is also evident that none of them can breathe at all.

9 (3)
Anaxagoras and Diogenes of Apollonia on Breathing (2)

Further, to claim that fish draw in air from the mouth, or rather from the water through the mouth, is an impossibility; for they do not have a windpipe because they do not have a lung, but their stomach is right next to their mouth, so that they must do the drawing with their stomach. But then the other animals too would do this; but, as things stand, they do not. And fish too, when they are out of water, would be seen to do this, but manifestly they do not. Further, in all the animals that breathe and draw in breath, we see a certain movement occurring in the part which does the drawing. But this does not happen in the case of fish; for they manifestly do not move any one of the parts in the area of the stomach except for the gills alone, and either in water or when thrown onto dry land they are gasping.

Further, when any animal that breathes dies by drowning in water, bubbles are formed out of the breath that is forcibly discharged—for example, when one forces **471ᵇ1**

turtles or frogs or any other kind of animal of this sort [to remain under water]. But this does not happen in the case of the fishes, no matter how people try to obtain this result, implying that fishes have no breath that is drawn in from outside. Also, the way in which they say breathing occurs in fishes should be possible for human beings too when they are under water; for if even fishes draw in air from the surrounding water by means of the mouth, why should human beings as well as other animals not do the same? We should also draw in the air through the mouth like the fishes do. So if indeed the former case were possible, this too should be possible; but since it is not possible, it is clearly not possible in the case of the latter either.

In addition, due to what cause do they die in the air and manifestly gasp as if they were suffocating, if indeed they breathe? For it is certainly not from lack of nourishment that this happens to them, which is the cause stated by Diogenes, simpleminded as he is. For he says that they draw in too much air when they are in the air, but a commensurate amount when they are under water, and they die because of this. But that should have been possible also in the case of terrestrial animals; but, as things stand, no terrestrial animal is suffocated by breathing too much.

Further, if all animals breathe, it is clear that the insects among them breathe too. But many insects manifestly continue to live when they are cut apart, not only into two parts but also into more—for example, the so-called centipedes. How, and by means of what [instrumental part], could they possibly breathe?

The principal cause of their not speaking well about these matters is both their being inexperienced with the internal parts of animals and their not grasping that nature does all things for the sake of something; for by inquiring about what end breathing is present in animals for the sake of, and by investigating the relevant parts such as the gills and the lung, they would have discovered the cause rather quickly.

10 (4)
Democritus on Breathing

Democritus does say that a certain result is obtained from breathing for the animals that breathe, when he claims that breathing prevents the soul from being squeezed out [of their body]. However, about the fact that nature has done this for the sake of
472a1 this end, he said nothing; for, generally speaking, like the other natural scientists, he too has not touched at all upon such a cause. He says that the soul and the heat are the same, namely, the primary shapes of the spherical atoms. When these atoms are separated out by the surrounding [air] that squeezes them out, he says that breathing comes to be an aid; for in the air there is a great number of such atoms, which he calls "understanding" and "soul." So when the animals breathe and the air comes in, these atoms come in along [with the air], and they counteract the squeezing, [thereby] preventing the release of the soul present in the animals.

And that is why living and dying depend on inhalation and exhalation; for when the surrounding air with its squeezing prevails, and what enters is no longer able to counteract it, because the animal is not able to breathe, then death occurs in animals. For death is the exit from the body of such [atomic] shapes resulting from the squeezing exerted by the surrounding [air]. But the cause due to which it is necessary for all animals to die at some time—not, however, at any random time but in accord with nature due to old age, but contrary to nature by force—he has not made clear at all. And yet, since this evidently happens at one time and not at another, he should have said whether the cause is internal or external. Nor does he speak at all about what the cause of the starting-point of breathing is, whether it is internal or external. For it is certainly not the case that understanding from outside provides the help, but rather the starting-point of breathing and of the ensuing movement comes from within, not due to being forced by the surrounding [air]. It is also absurd for the surrounding [air] to squeeze and at the same time, when it enters, to dilate.

These, then, are pretty much the things that Democritus said happen and how they do so. But if one should believe that what was said previously is true and not all animals breathe, one must suppose that he was given the cause not of all death but only in the case of animals that breathe. But it was not given well even in that case. This is clear from the facts and the sorts of things we all have experience of. For in hot spells, since we are hotter, we are more in need of breathing, and we all breathe more rapidly; but when the surrounding air is cold and contracts and solidifies the body, we hold our breath as a result. And yet it is at this time that what enters from without should prevent the squeezing out. But, as things stand, the contrary happens; for when too much heat is accumulated because breath is not let out, then people are in need of breathing; but after having inhaled, they must exhale. When they are hot, they breathe repeatedly, implying that they breathe for the sake of cooling, just when what [Democritus] says makes them add fire to fire.

11 (5)
Plato on Breathing

The circular thrust described in the *Timaeus*[12] has made no determinations at all as to the way in which the preservation of the heat occurs in the other animals, whether it is the same way or it is due to some other cause. For if breathing is present only in terrestrial animals, the cause due to which it belongs only to those animals must be stated; but if it belongs to the other animals as well, but in another way, this too must be determined, if indeed they are all able to breathe.

12. Plato, *Timaeus* 79a–e.

Further, the mode of causation is a fabrication. For [he says that] as the heat exits the body through the mouth, the surrounding air, being pushed and [thus] set in motion, falls through the open texture of the flesh into the same place whence the inner heat went out, exchanging places due to the fact that there is no void. But as the air becomes hot again, it exits through the same place and pushes the discharged air back into [the body] through the mouth. And indeed the animals keep on doing this all the time, inhaling and exhaling.

But it turns out, for those who hold this account, that exhaling takes place before inhaling. But it is the other way around. And there is a sign of this; for while inhaling and exhaling occur in alternation one after the other, animals exhale when they die, so the starting-point must be an inhaling.

Further, with respect to that for the sake of which this whole process is present in animals (I mean inhaling and exhaling), those who speak in this way have said nothing at all, but deal with it as if they were dealing with a mere coincidence. And yet, we see that these processes have control over life and death: when animals that breathe can no longer do so, then their destruction ensues.

Further, it is absurd to claim that we are unaware of the going out of the heat through the mouth and its subsequent coming back, while we are aware of the coming into the chest of the breath and its subsequent going out once it has been heated. And it is also absurd for inhaling to be the coming in of the heat; for it is manifestly the other way around; for what is exhaled is hot, whereas what is inhaled is cold. But when what is inhaled is hot, animals pant for breath; for because what enters is not
473a1 enough to cool them, they often gasp for more breath.

12 (6)
Respiration and Nutrition

But, at any rate, one should not take breathing to be for the sake of nutrition, believing that the inner fire is nourished by breath, and that when one breathes it is like adding combustible material to the fire, with exhalation occurring when the fire is nourished. For against this account we will repeat precisely the same arguments we also used against the previous ones; for this, or the analog of this, should also happen in the case of the other animals; for all animals possess vital heat. Then, with respect to the coming to be of heat from breath, in what way is the process to be accounted for? This is a fabrication; for we rather see that the heat comes to be from the nourishment. Also, the nourishment is taken in and the residue discharged through the same orifice; but we do not see this happen in other instances.

13 (7)
Empedocles on Breathing

Empedocles too speaks about breathing; however, he does not say for the sake of what it occurs, nor does he make it clear at all with respect to all animals whether they breathe or not. And when he speaks about breathing through the nostrils, he also thinks that he is speaking about the fundamental sort of breathing. For there is both breathing through the windpipe out the chest and breathing through the nostrils; but without the windpipe there is no breathing by means of the nostrils themselves. And when animals are deprived of breathing through the nostrils, they do not suffer any ill effects; but when they are deprived of breathing through the windpipe, they die. For nature makes use of breathing through the nostrils as a subsidiary end for smelling in some animals. That is precisely why almost all animals have a share in smell, while they do not all have the same perceptual organ. These matters are spoken about in a more perspicuous way elsewhere.[13]

[Empedocles] says that inhalation and exhalation occur through certain vessels in **473b1** which there is blood, though they are not full of blood but have ducts leading to the external air, which are smaller than the particles of blood[14] but large enough for those of the air. That is why, since blood is naturally moved up and down, when it is carried downward, air flows in and inhalation occurs, but when blood is carried upward air is driven out and exhalation occurs. He likens this process to what happens in clepsydras:

> They all inhale and exhale in the following way: in all of them, passages empty of blood,
> Made of flesh, are stretched deep inside the body,
> And at their openings the extremities of the nostrils
> Are pierced through and through with numerous furrows, so that blood
> Is kept inside but at the same time an easy passage for the breath is cut.
> Whenever, then, the tender blood rushes away from there,
> Bubbling breath rushes after it with furious swell,
> But when the blood runs back, the air is exhaled again—just as when a girl
> Playing with a clepsydra of shining bronze
> Places the opening of the pipe against her well-shaped hand,
> And immerses it in the tender body of silvery water,
> No liquid enters the vessel, but this is kept out
> By the mass of the air pressing from inside through the numerous holes,
> Until it recovers its dense flow, but then,
> As the breath leaves, an equal amount of water runs in.
> So, in the same way, when she holds water in the depths of the brazen vessel

13. *Sens.* 444a25–28, 444b7–28.
14. Reading αἵματος.

Blocking the opening and duct with her mortal hand,
The breath outside, longing to come inside, forces the liquid back,
At the gates of the harsh-sounding strainer,[15] controlling the ends [of the clepsydra],
Until she lets go with her hand; and then, again, in reverse from before,
As the breath comes in, an equal amount of water flows out.
So, in the same way, the tender blood surging through the limbs,
When it rushes back deep down inside [the body],
A stream of breath enters straightaway, raging in a swell;
But when the blood runs back, an equal amount is breathed out in return.[16]

Empedocles, then, says these things about breathing. But, as we said,[17] animals are evidently breathing through the windpipe at the same time as they are breathing through the mouth and through the nostrils. So if he is speaking about this sort of breathing, it is necessary to inquire how the account of the cause given [by him] will fit with it. For it manifestly happens the other way around. For it is by expanding the [relevant] place, just like the bellows in a blacksmith's forge, that animals inhale (and it is reasonable for the heat to expand, and for the blood to take the place of the heat), but by contracting it and pressing it down, as in the case of the bellows, they exhale. Except that in the case of the bellows, they do not take the air in and let it out again through the same passage, whereas those who breathe do so by the same passage.

But if Empedocles is speaking only about breathing with respect to the nostrils, he has made a great error; for there is no breathing that is peculiar to the nostrils, but the breath passes by the pipe next to the uvula where the extremity of the roof of the mouth is located, with part of it going through the nostrils connected by a passage, and part of it going through the mouth, likewise as it comes in and as it goes out.[18]

The statements made by others on the topic of breathing, then, present difficulties of these and this many sorts.

14 (8)
Why All Animals Need to Control Their Bodily Temperature

Since, as was stated previously,[19] being alive—that is, possessing a soul—involves a certain heat (for there is not even concoction, by which nourishing occurs in animals, without a soul or without heat; for all things accomplish their work by means of fire), that is precisely why it is necessary for a starting-point of this sort to be in the body's

15. I.e., the duct or tube of the clepsydra in which the breath makes gurgling sounds.
16. B100 DK.

19. 468b6–9; 470a19–20.

primary place, and indeed in the primary part of that place, where it is necessary for the primary nutritive soul also to be present. This is the place midway between the part that receives the nourishment and that from which the residue goes out. **474ᵇ1**

In bloodless animals it has no name, but in blooded animals this part is the heart; for the nourishment out of which the parts of blooded animals come to be is of the nature of blood. And both the blood and the blood vessels must have the same starting-point; for one is for the sake of the other, like a vessel and a container. The starting-point of the blood vessels in blooded animals is the heart; for they do not extend through the heart but rather they are all attached to it. This is clear to us from the *Dissections*.

The other capacities of the soul cannot be present without the nutritive soul (due to what cause was stated previously in the *De Anima*[20]), and this cannot be present without natural fire, in which nature has set it aglow. Fire is destroyed, as was stated previously,[21] by extinction and exhaustion. Extinction is destruction by contraries, which is precisely why fire is extinguished in a mass by the surrounding coldness and more quickly when it is scattered. This sort of destruction is violent in animate and inanimate things alike. For when the animal is either cut apart by instruments or is frozen due to an excess of cold, it dies. Exhaustion, on the other hand, occurs through a large quantity of heat; for when the surrounding heat is excessive, and the animal does not take in nourishment, it dies by being burned out, not by becoming cold but by being exhausted. As a result, there must be cooling if the animal is going to secure its preservation; for this aids against this sort of destruction.

15 (9)
Insects and Other Bloodless Animals

Since some animals are aquatic while others spend their life on land, in the altogether small and bloodless ones the cooling that results from the surrounding water or air is enough aid against this sort of destruction; for having little heat they need little aid. That is also why almost all such animals are short-lived; for since they are small, it takes little to tilt the balance in either direction.[22]

But of the insects (for all insects are bloodless), all those that are longer-lived are split below the diaphragm so as to be cooled through the membrane which is rather thin. For since they are hotter [than the other insects], they are in need of more cooling, for example, bees (for some bees live up to seven years) and all the others that buzz, for example, wasps, cockchafers, and crickets. They make a sound by means of breath, as if they are panting. For in their diaphragm itself, by means of their innate breath expanding and contracting, a rubbing against the membrane occurs; for they **475ª1**

21. 469ᵇ21–470ª5.
22. I.e., either toward loss of heat and death or retention of heat and life. See 478ª16.

move this place like animals that breathe air from the outside with their lung and fish with their gills. For much the same happens if one suffocates one of the animals that breathe by holding the mouth shut. For these too will make this heaving movement with their lung: but for them such a movement does not produce enough cooling, while it is enough for insects. And it is by rubbing against their membrane that insects make their buzzing sound, as we say, just like children do when they blow through reeds bored with holes covered by a thin membrane. For it is because of this that cicadas too sing their songs; for they are hotter [than the other insects] and they are split below their diaphragm, while those that do not sing have this part unsplit.

Among animals that are blooded[23] and have a lung, but a lung with little blood and spongy, some, because of this, can live without breathing for a long time, because the lung can expand greatly since it has little blood and liquid; for its own movement suffices to keep [the animal] cool for a long time. In the end, though, it cannot do so, and [the animal] is suffocated by not breathing, as was also said previously;[24] for the sort of exhaustion that occurs in the absence of cooling is called "suffocation," and we say that the animals that die in this way are suffocated.

That, among animals, insects do not breathe was also said previously,[25] and this is also manifest in the case of small animals like flies and bees; for they can swim in liquids for a long time if the latter are not too cold or too hot (although those with little capacity try to breathe more frequently). But they die and are said to suffocate when their stomach is filled [with liquid] and the heat in their diaphragm is dissipated. And that is also why they revive after having spent some time in [warm] ash.

All aquatic animals that are bloodless live longer in the air than those that are blooded and take in seawater as, for example, fishes do. For, because they have little heat, the air is enough to cool them for a long time—for example, the soft-shelled animals and the octopuses. In the end, however, the little heat they have does not suffice to keep them alive.[26] Thus many fishes too live in the earth, yet in a motionless state, and are found by digging them up. For those animals that either have no lung at all or else a bloodless one need to be cooled less frequently.

16 (10)
Blooded Animals

Concerning the bloodless animals, then, it was stated[27] that in some cases it is the surrounding air that aids with preserving life, while in other cases it is the surrounding liquid. But as for blooded animals that have a heart, all those that have a lung

23. Reading ἐναίμων.
24. 470b18–24.
25. 471b19–23.
26. Accepting the seclusion of διὰ.
27. 474b25–475a20.

take in air and produce their cooling through inhalation and exhalation. And animals that are live-bearing internally and not only externally have a lung (for the selachians are live-bearing, but not internally), and, among the egg-laying animals, the winged ones, like the birds, and the hard-scaled ones, like the turtles, lizards, and snakes. But while the former have a blooded lung, most of the latter have a spongy one. That is also why they make more infrequent use of breathing, as was also stated previously.[28] All animals that pass their time, or make their life, in water make use of breathing—for example, the water-snake kind, the frog kind, the crocodile kind, the freshwater-turtle kind, sea and land turtles, and seals. For all these animals, and similar ones, give birth on dry land and sleep either on dry land or in water, holding their mouth above water for breathing,

But all animals that have gills cool themselves by taking in water; both the so-called **476^{a}1** selachian kind and the other footless animals have gills. And all fishes are footless; for the parts they in fact have are said to be what they are[29] in virtue of their similarity to wings (*pteruges*). Of those that have feet only one among those that have been observed has gills, the animal called a "water newt."

But no animal has yet to be seen that has both a lung and gills. The cause is that a lung is for sake of cooling by means of breath (it seems that the lung (*pneumôn*) has taken its name from being a receptacle of the breath (*pneuma*)), while gills are for cooling by means of water. One instrument is useful for one work, and one sort of cooling is enough for all animals; so, since we see nature doing nothing pointless, and since one of the two sorts of cooling would be pointless, because of this some animals have gills while others have a lung, but none has both.

17 (11)
Blooded Animals Continued

Since each animal needs nourishment for its existence, and cooling for its preservation, nature uses the same instrument for both, just as in a few animals it uses the tongue for flavors as well as for speech, so in animals with a lung it uses what is called a "mouth" for working on the nourishment as well as for inhaling and exhaling. But in animals that do not have a lung and do not breathe, the mouth is for the working on the nourishment, while for those that are in need of cooling, the nature of the gills is present for cooling.

As for how the capacity of the mentioned instruments produces the cooling, we will say later on.[30] But with a view to the nourishment's not hindering [cooling], it happens in much the same way with the animals that breathe and with those that take in water; for they do not breathe at the same time as they admit nourishment.

28. $470^{b}12$–15.
29. I.e., fins (*pterugia*).
30. $480^{a}16$–$480^{b}20$.

Otherwise, they would be suffocated due to the nourishment, whether dry or liquid, going through the windpipe into the lung; for the windpipe is located before the esophagus, through which the nourishment travels to what is called the "stomach." In four-footed blooded animals the windpipe has the epiglottis as a sort of lid. But there is no epiglottis added to the windpipe in birds and in egg-laying four-footed animals; instead, they produce the same result by contraction. For when they take in their nourishment, the latter animals contract their windpipe, while the former close the epiglottis; and when the nourishment has gone by, the latter expand the windpipe, while the former open the epiglottis and admit breath for cooling.

As for the animals that have gills, it is only after they have expelled the water through the gills that they admit nourishment through the mouth; for they do not have a windpipe, so they cannot be harmed in any way by the entrance of the water but only if it goes into the stomach. That is why they expel [water] and take nourishment quickly, have sharp interlocking teeth, and pretty much all are sawtoothed; for they cannot chew the nourishment.

18 (12)
Cetaceans

Among aquatic animals, one might raise a puzzle about cetaceans (for example, about dolphins, whales, and those other animals having a so-called [blowhole] pipe), but they too admit of an account. For they are footless and, though having a lung, take in seawater. The cause of this is what has now been stated;[31] for they do not take in liquid for the sake of cooling. For this is accomplished by their breathing; for they have a lung. That is also why they sleep holding their mouths above water and snore (at any rate, dolphins do). Further, when they are caught in nets, they are quickly suffocated due to their not breathing; that is also why such animals are seen coming to the surface of the sea for the sake of breathing. But since it is necessary for them to get their nourishment in water, they must expel the water they take in, and that is why they all have a pipe. After taking in the water, just like fish do through the gills, these animals push it out through the pipe. The location of the pipe is also a sign of this; for it leads to none of the parts filled with blood, but instead has its position in front of the brain.

Due to the same thing both the soft-bodied and the soft-shelled animals take in water, I mean the animals called "crayfishes" and the crabs. None of them are in need of cooling at all; for each of them possesses little heat and is bloodless, so that they are cooled down sufficiently by the surrounding water. But because of the nourishment, they expel the water to prevent it from flowing in at the same time as they swallow. Soft-shelled animals such as crabs and crayfishes expel the water through the opercula

31. Reference unclear.

located beside their shaggy parts, while cuttlefish and the octopuses do it through the hallow area above what is called their head. These animals are written about with more exactness in the *History of Animals*.[32]

Concerning the taking in of water, then, it has been stated that it occurs because of cooling and because the animals that are aquatic by nature need to take in their nourishment from the water.

19 (13)
Cooling Explained

In what way cooling occurs in animals that breathe and also in those that have gills must next be spoken about. It was stated previously[33] that all animals that have a lung breathe. But as to why some animals have this part, and why those that have it are in need of breathing, the cause of having it is that the more estimable animals have a greater quantity of heat; for at the same time they must also have a more estimable soul. For these animals are more estimable than the nature of plants.[34] That is also why the animals that have the most blooded lung and the most heat are greater in size, and the animal that makes use of the purest and greatest quantity of blood is the one that is most upright of all, namely, the human being, which alone has the upper part aligned with the upper part of the universe because of having this part.[35] So this part must be posited as the cause of the substance in the human being as well as in the other animals, just like any other. They have it, then, for the sake of this.

But one must think that the cause that is of necessity[36] and the moving one compose animals of this sort just as they have composed many others that are not of this sort. For some living beings are made of a greater quantity of earth, like the plant kind, while others are made of a greater quantity of water, like the aquatic-animal kind. But when it comes to winged and terrestrial animals, the former are made of a greater quantity of air, the latter of fire. It is in its proper place, though each has its position.

20 (14)
Empedocles on Why Animals Dwell in Water

Empedocles did not speak well when he said that animals with the greatest quantity of heat and fire are aquatic, avoiding the excess of heat in their nature, so that, since they are lacking in the cold and the wet, they can be restored in accord with their **477b1**

32. 4.1–3.
33. 476b11–12.
34. Reading φυτῶν.
35. I.e., a lung filled with the purest and largest quantity of blood.
36. I.e., the material one.

place, which has a contrary quality; for he says that the wet has less heat than the air. But it is wholly absurd to suppose that each of these animals, being generated on dry land, could change its place and go into the water; for most of them are also pretty much footless. But Empedocles says that their initial composition occurred on dry land, which they fled to go into water. Further, it is not evident that aquatic animals are hotter than terrestrial ones; for some of them are altogether bloodless, while others have little blood.

Which living beings one should say are hot and which cold has been investigated[37] taking each kind by itself. But concerning the cause that Empedocles has stated, though in a way what he is seeking to show is reasonable, what he in fact says is certainly not true. For while those that have excesses in their [bodily] states are preserved by contrary places and seasons, their nature is best preserved in their proper places. For the matter out of which each animal is composed is not the same as its states and dispositions. I mean, for example, if nature had composed something out of wax, it would not preserve this thing by putting it in a hot place, nor if it had composed it out of ice. For the thing would have been destroyed quickly by its contrary; for the hot melts what is composed by its contrary. Nor if it had composed something out of salt or niter would nature have deposited it in water by transporting it; for water destroys the things composed by what is dry.

If, then, the wet and the dry serve as matter for all bodies, it is reasonable for the living things made out of the wet and the cold to dwell in wet places,[38] and for those made out of the dry to dwell in a dry place. Because of this, trees do not grow in water but on dry land. And yet, it is a consequence of his account that they should be placed in water because they are exceedingly dry, just as he says happens to what is exceedingly fiery; for they would have gone into it not because it is cold but because it is wet.

The natures of the matter, then, are of the same sort as is the place in which they are found: in water, wet natures; on dry land, dry natures; and in air, hot natures. However, the states that are excessively hot are better preserved when placed in a cold place, those excessively cold in a hot place; for the place reduces to the mean the excess in the states. This, then, must be sought in the places proper to each sort of matter and in accord with the change in the seasons, which is common to all; for while the states may be contrary to the places, this is impossible for the matter.

About the fact, then, that it is not because of the heat of their nature that some animals are aquatic and others terrestrial, as Empedocles says, and why some do not have a lung while others do, let this much be said.

37. *PA* 648ᵃ36–ᵇ10.

38. Retaining καὶ ψυχροῦ and accepting the seclusion of καὶ εἰ ψυχρά, ἔσται ἐν ψυχρῷ.

21 (15)
Breathing Explained

But why do the animals that have a lung take in air and breathe, especially all those that have a blooded lung? The cause of breathing is the lung, which is spongy and filled with passages. And, among those that are called "viscera," this part is the most filled with blood. All animals, then, that have a blooded lung are in need of rapid cooling because it takes little to tilt the balance of their vital heat,[39] with the cooling penetrating inside the whole lung on account of the large quantity of blood and heat. And the air can do both these things easily. Because it has a fine-grained nature, it slips through everywhere and cools the lung quickly, while water is the contrary. And why those animals that have a blooded lung breathe the most is clear from these considerations; for the part that is hotter is in need of more cooling, and at the same time [as it cools the lung] the breath travels easily all the way to the starting-point of the heat in the heart.

22 (16)
The Relation of the Heart to the Lung and the Gills

As for the way in which the heart is connected by a passage to the lung, one must observe it from the dissections and from what is written in the *History of Animals*.[40] In general, the nature of animals is in need of cooling because of the setting aglow in the heart of the soul. This cooling is produced by breathing in all animals that have not only a heart but also a lung. But all those that have a heart but not a lung—for example, the fishes, because their nature is aquatic—produce the cooling by means of water through the gills.

One must observe the position of the heart with respect to the gills visually from the dissections,[41] but for exactness from the *History of Animals*.[42] But to speak in a summary fashion also now, the parts are related in the following way. For while the heart might not seem to have the same position in the terrestrial animals and the fishes, it in fact has the same one; for the heart has its pointy end where the animals incline their heads. But since the heads are not inclined in the same way in the terrestrial animals and in the fishes, the heart [in the case of the fishes] has its pointy end toward the mouth. From the extremity of the heart a sinewy vessel-like pipe extends to the center where all the gills join together with one another. This is the largest one, but on either side of the heart others also extend to the extremity of **478b1**

39. 474b31.
40. 496a27–34.
41. This may be a reference to actual dissections.
42. 507a2–10.

the gills, through which the cooling reaches all the way to the heart, with the water always passing through the gills.

In the same way, in the animals that breathe, the chest moves up and down frequently while they take in and let out their breath, just like the gills in the fishes. And the animals that breathe are suffocated when there is little air and it remains [always] the same; for in either case they quickly become hot; for contact with the blood heats in either case, and being hot, it prevents the cooling of the animal. And when the animals that breathe cannot move their lung, or the aquatic animals their gills, due to an affection or due to old age, at that point death must ensue.

23 (17)
Natural Death

Birth and death are common to all animals, but the ways in which they happen differ in form; for passing away is not without difference, although there is something in common to all cases. One sort of death is violent, another natural: it is violent when the starting-point is external, natural when the starting-point is within the animal, and the composition of the part is such [as to be liable to it] from the start, rather than an acquired affection. In plants [the process leading to natural death] is called "withering," in animals "aging." Death and passing away happen alike to all the living beings that are not incomplete. They occur in the incomplete ones in a closely similar but distinct way. By "incomplete" I mean, for example, eggs and the seeds of plants (all those that are without roots). To all of them passing away comes about owing to a failure of a certain sort of heat, which in complete living beings is the one found in the part in which the starting-point of their substance resides. This starting-point is located, as was stated previously,[43] where the up and the down are joined together: in plants midway between the stem and the root, in blooded animals in the heart, and in bloodless animals in the analogous part. Some of these living beings have several starting-points potentially, yet not indeed actively. That is also why some insects continue to live after they are divided, and why all blooded animals that are not too full of life continue to live for a long time when their heart is removed—for example, the turtles, and they move their feet if their shell is attached to them, because their nature is not put together well, but it is much the same as in the insects.

The starting-point of life fails in those that have one, whenever the heat associated with it is no longer cooled; for, as has been said many times,[44] it is consumed by itself. Whenever, then, the lung in some animals and the gills in others have hardened, because over a long time the lung or the gills have dried up and become earthy, they

43. 467ᵇ32–468ᵃ5.
44. 469ᵇ26–470ᵃ5; 474ᵇ20–24; 474ᵃ27–29.

are no longer able to move these parts, that is, to expand and contract them. Finally, they come to a halt and the fire dies out completely exhausted.

That is also why, beset even by a minor affection, animals die quickly when in old age. For because there is little heat, since most of it has been breathed away in the long-lived life, whatever strain occurs on the relevant part will extinguish it quickly, as if there was in this part a feeble and small flame that is extinguished by a slight movement. That is also why death in old age is painless; for people die without any violent suffering occurring to them, and the release of the soul is entirely imperceptible. And all diseases that make the lung hard either due to tumors, to residues, or to an excess of morbid heat, as in the case of fevers, shorten the breath due to the inability of the lung to make its full extension upward and contraction. In the end, when the animals are no longer able to move it at all, they die after having exhaled their last breath.

24 (18)
A Few Definitions

Generation is the first participation in the heat of the nutritive soul; life is the persistence of this participation. Youth is the growth of the primary part that has the capacity to cool, old age is the decline of this part; the prime of life is midway between them. End of life and passing away: the violent one is the extinction and exhaustion of the heat (a living being may be destroyed by either cause), while the natural one is the exhaustion of the same thing over a long time occurring at the very end of life. In plants this is called "withering," and in animals "death." Death in old age is the exhaustion of this part because of its inability to cool due to old age.

479b1

What generation, life, and death are, then, and due to what causes they occur in animals, has been stated.

25 (19)
Suffocation Explained

It is also clear from these considerations due to what cause the breathing animals are suffocated in water, the fishes in the air; for, in the latter, cooling takes place through water and in the former through air, and they are each deprived of the one or the other when they change their places. And the cause of the movement, for fish of the gills and for breathing animals of the lung (due to the expansion or contraction of which the ones inhale and exhale air while the others take in and take out water) as well as the composition of their bodily instrument, are as follows.[45]

45. Aristotle does not fulfill this promise until he has dealt with the heart in Chapter 26. The connection between the swelling of the heart and the need for cooling is made apparent at the outset of Chapter 27.

26 (20)
Palpitation and Pulsation

There are three occurrences involving the heart that are thought to have the same nature, but in fact they do not have the same one: palpitation, beating, and breathing.

Palpitation is the compression of the heat in the heart due to a cooling caused by residues or colliquescences[46]—for example, in the disease called "tremors" as well as in other diseases. But it occurs also in fits of fear; for people who are frightened become cold in the upper part [of their body], while the heat produces the palpitation by withdrawing and concentrating [in the heart]. It is compressed into such a small area that sometimes the heat is extinguished, and the animals die of fright and from a morbid affection.

The beating that occurs in the heart, which, as can be seen, is produced continuously, is like [the throbbing caused by] abscesses, which is a movement that is produced along with pain because the change in the blood is against nature and goes on until there is a discharge of pus once it is concocted. This affection is like boiling, for boiling occurs when liquid is made breathy by heat; for it expands due to its increase in bulk. But while the end-point in abscesses—since if the liquid does not evaporate, it becomes thicker—is putrefaction, in boiling it is the liquid's escape from its containers.

In the heart, however, the heat-induced swelling up of the liquid resulting from the nourishment, which is constantly flowing in, causes pulsation as it rises to the outer wall of the heart. And this process is always going on without interruption, for there is a constant inflow of the liquid from which the nature of the blood is produced. For it is in the heart that the blood is first crafted. This is clear at the initial stage of generation; for though the blood vessels are not yet determined, the heart manifestly contains blood. And that is why the heart beats more in the young than in the old; for the exhalation[47] is more abundant in the young.

And all the blood vessels beat, and they do so at the same time as each other because they are attached to the heart. And the heart is always in movement, so that they are too, and at the same time as each other, when the heart is in movement.

Palpitation, then, is the pushing back of the heart against the compression caused by the cold, while beating is the vaporization of the heated liquid.

27 (21)
The Mechanics of Breathing Explained

Breathing occurs when there is an increase of the heat in which the nutritive starting-point resides. For just as the other parts are also in need of nourishment, so is this

46. *GA* 724ᵇ26–28.
47. *Somn.* 456ᵇ2–5.

part,[48] and more so than the others; for it is the cause of the nourishment for the others. It is necessary, then, for the heat, as it increases, to cause the instrument to expand. And one must suppose that the composition of this instrument is much the same as the bellows in a blacksmith's forge (for the lung and the heart are not far from having this sort of shape). But something of this sort must be double; for the nutritive capacity must be in the middle of the cooling capacity.

As the heat increases in quantity, it expands, and as it expands, it must also cause the surrounding part to expand. This is precisely what breathing animals are seen to do; for they expand their chest because the starting-point situated in this sort of part does this very same thing. And as the chest expands, it is necessary for the external air, which is cold, to rush in as into a bellows, and having a chilling effect it extinguishes the excess of fire. But just as the increase [in the heat] expands this part, so its decrease must contract it; and as this part contracts, it is necessary for the air that entered to go out again, entering cold but going out hot due to its being in contact with the heat present in this part. And this is especially the case in animals that have a blooded lung; for the air must go into the many pipe-like passages in the lung, alongside each of which there extends a blood vessel, so that the whole lung seems to be full of blood. The entrance of the air is called "inhalation," and its exit "exhalation." And this process goes on without interruption as long as the animal is alive and moves this part without interruption; and that is why being alive consists in inhalation and exhalation.

480^{b}1

It is in the same way that the movement of the gills occurs in the fishes too. For when the heat in the blood present throughout their bodily parts expands, the gills expand as well, and let the water pass through. As the water goes into their body through the ducts toward the heart and cools it, the gills contract and expel the water. As the heat in the heart constantly expands, it constantly receives water and expels it again when it is cooled. That is why the end of living and non-living in animals that breathe consists in breathing and in animals with gills in taking in water.

As regards the investigation of life and death and related matters, pretty much everything has been spoken about. But concerning health and disease, it is not only for the doctor but also for the natural scientist to give their causes, at least up to a point. And it must not be overlooked how different these two endeavors are, and how they are theoretically concerned with different subjects, since what happens testifies that their study follows the same course up to a point. For those doctors who are subtle and inquisitive have something to say about nature and claim to take their starting-points from there, while the most accomplished among those who are concerned with the study of nature end up dealing with the starting-points of medicine.[49]

48. I.e., the heart.
49. *Sens.* 436^{a}17–^{b}1.

ON THE HISTORY OF ANIMALS*

BOOK 1

1.1
Parts of Animals and How They Differ; Forms and Kinds; Differences in Animals: Lives, Actions, Characters, and Parts

Among the parts present in animals, some are incomposite, those that divide into uniform parts (for example, flesh into flesh), and the others composite, those that divide into non-uniform ones (for example, the hand does not divide into hands, nor the face into faces). Among the latter, some are called not only "parts" but "members."[1] Of this sort are whichever parts, while being wholes, have other parts within them—for example, the head, the leg, the hand, the arm as a whole, and the thorax;[2] for these are themselves whole parts, and there are other parts belonging to them. All the non-uniform parts are composed of uniform ones—for example, the hand of flesh, sinews, and bones.

Some of the animals have, with respect to each other, all their parts the same; others have parts that are distinct. Some parts are the same in form—for example, one human being's nose and eye and another human being's nose and eye, one's flesh and another's, one's bone and another's. And it is the same way with a horse, and whichever other animals we say are the same as each other in form; for as the whole is to the whole, so too each part is to each part. In other cases, though they are the same [in form], they differ by excess and deficiency, all those whose kind is the same. By "kind" I mean, for example, the bird and the fish; for each of these exhibits difference with respect to kind, and there are many forms of fishes and of birds.

Pretty much most of the parts in animals differ in the contrarieties of their affections (for example, of colors and shapes), in that some have the same ones more, others less, and additionally in greater or fewer number, and larger or smaller size, and, in general, in excess or deficiency. Thus, some are soft-fleshed, others hard-fleshed; some have a long beak, others a short one; some have many feathers, others few. Nonetheless, even in the cases we are considering, it sometimes happens that different

* Translated by C. D. C. Reeve. Text: P. Louis, *Histoire des Animaux* (Paris, 1964–1969), except where indicated. A *historia* is not a history, in our sense of the term, but an inquiry. Animals and animal parts of uncertain identity have their Greek names italicized and uninflected.

1. In many cases these are limbs.

2. 491^{a}29–30.

ones have different parts—for example, some have spurs, others do not, some have crests, others do not. But (one might almost say) most of the parts, and those from which the whole bulk of the body is composed, are either the same [in form] or differ by way of a contrariety, that is, with respect to excess or deficiency; for the more and less may be taken as a sort of excess or deficiency.

Some animals, however, have parts that are neither the same in form nor in excess or deficiency, but analogous—for example, bone in relation to spine, nail to hoof, and hand to claw, feather to soft-scale; for what in the bird is feather in the fish is soft-scale.

These are the ways in which all the animals are distinct or the same as regards their parts; further, they do so as regards the position of the parts; for many animals have the same parts, but differently positioned—for example, some have breasts on the chest, some near the thighs.

487^a1 Among the uniform parts, some are soft and liquid, others dry and solid, and those that are liquid may be so generally or only while in their natural condition—for example, blood, serum, fat, suet, marrow, semen, bile, milk (in those that have it), flesh, and the analogs of these. And further, in another way, the residues—for example, phlegm and the sediments[3] of the bowel and of the bladder. And examples of dry and hard are sinew, skin, blood vessel, hair, bone, cartilage, nail, horn (for it is a homonym related to the part[4] when due to the shape the whole is also said to be horn), and further, those analogous to them.

The differences in the animals are in accord with their lives, actions, characters, and parts, about which we speak first in outline, and later speak scientifically about each kind.

The differences with respect to their lives, actions, and characters are of the following sorts: some animals are aquatic, others terrestrial. But the aquatic ones are twofold: some because they live and get their nourishment in a liquid, take in liquid and emit it, and when deprived of it are incapable of living (for example, this happens in the case of many of the fishes); others get their nourishment and pass their time in liquid, yet do not take in liquid, but rather air, and generate offspring outside the liquid. Many of these too are footed (for example, the otter, the *latax*, and the crocodile); many are winged (for example, the puffin and the grebe); and many are footless (for example, the water snake). And some animals, though they get their nourishment in a liquid and are not capable of living out of it, are yet not capable of taking in either water or air (for example, the anemones and the shellfishes).

Among the aquatic animals, some are in the sea, others in rivers, others in lakes, others in marshes (for example, the fishing frog[5] and the water newt).

3. I.e., residues.
4. Reading πρὸς τὸ μέρος.
5. Or anglerfish (*Lophius piscatorious*).

Among the terrestrial ones, some take in and emit air, which is called "inhalation and exhalation" (for example, the human being and all the terrestrial ones that have a lung), others do not take in air, although they live and get their nourishment on land (for example, the wasp, the bee, and the other insects). (I call "insects" (*entoma*) those ones that have sections (*entoma*) on their body, whether on their underneath parts only, or both there and on their back parts). And many of the terrestrial animals, as was said,[6] get their nourishment from liquid, while none of the aquatic ones that takes in seawater does so from land.

Some animals first live in liquid, then change to another shape and live out of it—for example, *aspis*[7] in rivers are a case of this; for gadflies come from them.

Further, some animals are stationary, while others change with respect to place. The stationary ones are in liquid; none of the terrestrial ones is stationary. But in liquid we find many that live by being attached to something—for example, many kinds of shellfishes. The sponge too seems to have a sort of perception. A sign of this is that it is more difficult to detach, unless the movement is produced surreptitiously—or so they say. On the other hand, some both attach and detach themselves—for example, a certain kind of so-called anemones (for some of these detach themselves at night and feed). Many animals, though detached, are unmoving—for example, the shellfishes and so-called sea cucumbers. But some are swimmers—for example, the fishes, the soft-bodied animals, the soft-shelled animals (for example, the crayfishes). And some move by walking—for example, the crab kind; for, though they are aquatic, their nature is to move by walking.

Among the terrestrial animals, some are winged (such as birds and bees, and these are so in a different way from each other), others footed. And among the footed ones, some move by walking, others creep, and others wiggle. None though is only a flyer, as a fish is only a swimmer; for even the skin-winged animals move by walking—even bats have feet (as also does the seal,[8] which has docked feet).

Among the birds, some have bad feet, because of which they are called "footless birds." But this sort of small bird is a flyer. And the ones that are like it are also pretty much flyers and have bad feet—for example, the swallow and the swift; for all birds of this sort have like ways and like feathers, and their looks are nearly the same as each other. The footless bird is visible in every season, the swift when it has been raining in summer; for then it is seen and caught, but, in general, this bird is rare. But many animals are walkers and flyers.

There are also differences of this sort with respect to lives and actions. For some animals are gregarious, others solitary, whether they are footed, winged, swimmers, or play a double game.[9] Also, of the gregarious ones and the solitary ones, some are political, while others are more dispersed. Examples of gregarious animals are, among

6. 487ᵃ19–20.
7. Reading ἀσπίδων. The text and the identity of the insect is uncertain, as at 601ᵃ2.
8. Reading ὡς καὶ τῇ φώκῃ.
9. They both walk and swim, or fly and walk.

birds, the pigeon kind, the crane, and the swan (no crook-taloned bird is gregarious); among swimmers, many kinds of fishes—for example, the so-called migratory fishes (the tuna, the young tuna,[10] and the bonito). The human being, however, plays a double game.

The political animals are those among which there is some single work common to all, which is precisely what not all herd animals produce. Of this sort are the human being, the bee, the wasp, the ant, and the crane. Also, of these some are under a leader, while others are without a ruler—for example, the crane and the bee kind are under a ruler, the ants and innumerable others are without a ruler. Among the herd animals and the solitary ones, some stay in one place, while others roam around.

Also, some are carnivorous, others fruit-eating, others omnivorous, while some eat a diet special to them—for example, the bee kind and the spider kind; for bees use honey and a few other sweet stuffs for their nourishment, spiders live by catching flies, and other animals use fish for their nourishment. Again, some catch their nourishment, and some store it up, while others do not.

Also, some have habitations, some are without habitations: having habitations—for example, the mole, the mouse, the ant, the bee; without habitations—many insects and four-footed animals. Further, in their places of habitation, some are hole-dwellers (for example, the lizards and the snakes), others above ground (for example, the horses and the dogs). Also, some are burrowers, others non-burrowers. Also, some are nocturnal (for example, the owl and the bat), others live in daylight.

Further, some are tame, others wild. And some are always so: some always tame (for example, the human being[11] and the mule), some always wild (like the leopard and the wolf), others capable of being quickly tamed (for example, the elephant). Further, there is another way [of dividing them]; for every animal kind that is tame is wild too (for example, the horses, the cows, the pigs, the human beings, the sheep, the goats, and the dogs).

Also, some emit sounds, others are mute, and others have a voice, and of these some have speech, while others are unable to emit articulate sounds; some are vocal, others silent; some are singers, others songless. But it is common to all of them to sing
488b1 or vocalize most around the times of mating.

Also, some live in the fields (for example, the wood pigeon), others in the mountains (for example, the hoopoe), some alongside human beings (for example, the pigeon).

Also, some are lecherous—for example, the partridge kind and the chicken kind; others are inclined to chastity—for example, the raven-like kind of birds; for these rarely mate.

Also, of marine animals, some are deep-sea dwellers, others frequent the shore, others grow on or among rocks.

10. 571a11.
11. Reading ἄνθρωπος.

Further, some defend themselves, others take shelter. The defensive ones are those that, when injured, attack others or defend themselves; while those that take shelter are those that have some place of shelter[12] in themselves against suffering any injury.

Animals also differ in the following ways with respect to character. Some are mild-mannered, spiritless, and non-aggressive (for example, the cow); others are spirited, aggressive, and ineducable (for example, the wild pig); others are practically wise and cowardly (for example, the deer and the hare); others are servile and treacherous (for example, the snake[13]); others free, courageous, and well-bred (for example, the lion); others are true to their stock, wild, and treacherous (for example, the wolf); for an animal is well-bred if it comes from good stock; it is true to its stock in not being a degeneration from its own nature.

Also, some are cunning and malicious (for example, the fox); others are spirited, affectionate, and fawning (for example, the dog); others are mild-mannered and easily tamed (for example, the elephant); others are shy and on their guard (for example, the goose); others are envious and vain (for example, the peacock). But of the animals only human beings are capable of deliberation. Also, many animals share in memory and are capable of being taught, but no other is capable of recollecting except the human being.[14]

About each of the kinds of animals, and about their characters and modes of life, we will speak with exactness later on.[15]

1.2
Parts for Nourishment and Excretion

All animals have in common the parts with which they take in nourishment and the parts they take it into. And these are the same and distinct in the ways described: with respect to form, with respect to excess and deficiency, or by analogy, or differing in position.

In addition to these, most animals have other parts in common with each other as well with which they emit the residue of the nourishment; for not all animals have it. The part with which they take it in is called a "mouth," the one they take it into, a "stomach." The remaining parts have many names. **489^{a}1**

Because the residues are twofold, those animals that have a part receptive of the liquid residue also have one receptive of [that from] the dry nourishment, but those that have the latter do not all have the former. That is why the ones that have a bladder also have a bowel, while those that have a bowel do not all have a bladder (for the part receptive of the liquid residue is named a "bladder," and of the dry, a "bowel").

12. E.g., a shell.
13. Reading ὄφις.
14. *Mem*. 453^{a}9–14.
15. Books 8–9.

1.3
Parts for the Emission of Seed

Many of the remaining animals have these parts, and further, a part by which they emit seed. And of those in which the capacity to generate animals belongs, in one, emission is within the animal itself, in the other, it is within another. The one in which emission is within itself is called the "female," within another, the "male" (in some, there is neither male nor female). Also, the parts that are for this crafting [of animals] differ in form; for one has a uterus, another its analog.[16]

These, then, are the parts most necessary to animals: on the one hand, those that belong to all animals, on the other, those that belong to most.

To all animals only one perceptual modality belongs in common, touch, so that the part in which it naturally occurs is nameless; for it is the same part in some animals, in others the analog.

1.4
Liquid in Animals: Blood and Blood Vessel

Every animal possesses liquid too, and if it is deprived of it, either by nature or by force, it passes away. Further, what it is in is another [part]. In some, this is blood and blood vessel, in others the analog of these. But the latter are incomplete—for example, fiber[17] and serum.

Touch is situated in a uniform part (for example, flesh or something of this sort), and, in general, in sanguineous parts, in those that have blood; in the others, it is situated in their analog, but in all cases in a uniform part. The productive capacities, on the other hand, are situated in the non-uniform parts—for example, the capacity for working on nourishment in the mouth, the one for movement with respect to place in the feet, the wings, or their analog.

In addition to this, some animals are blooded (for example, the human being, the horse, and all those that, when complete, are footless, two-footed, or four-footed), others bloodless (for example, the bee, the wasp, and, of the marine animals, the cuttlefish and the crayfish, and all those with more than four feet).

1.5
Live-Bearing, Egg-Laying, and Larvae-Generating Animals: Feet, Fins, and Wings

Also, some animals are live-bearing, others egg-laying, others larvae-generating. Examples of the live-bearing ones are the human being, the horse, the seal, and all

16. *GA* 754[a]1–2.
17. 515[b]27.

the others that have hair. And, of aquatic animals, the cetaceans (for example, the **489^{b}1**
dolphin), and the so-called selachians. Some of these have a [blowhole] pipe but no
gills (for example, the dolphin and the whale). The dolphin's pipe is through its back,
the whale's is in its forehead. Others have uncovered gills (for example, the selachians, 5
the sharks, and the rays).

Among the embryos that are complete, what is called an "egg" is the one from which the animal offspring comes to be, from one part of which comes the starting-point, while the other is nourishment for the offspring.[18] A larva, on the other hand, is that from the whole of which the whole of the animal comes to be, as the embryo becomes articulated and grows.

Some of the live-bearing animals are internally egg-laying (for example, the sela- 10
chians), others are internally live-bearing (for example, the human being and the horse). What is brought to light when the embryo has reached completion is in some cases a living animal, in some an egg, in some a larva. Among eggs, some are hard-shelled and two-colored (for example, those of the birds), others soft-skinned and single-colored (for example, those of the selachians). And of larvae, some are 15
mobile from the outset, others immobile. But these things must be spoken about with exactness later on in the *Generation [of Animals]*.[19]

Further, some animals have feet, others are footless. Among those having feet, some have two feet (for example, the human being and the bird, and these alone), 20
others four feet (the lizard and the dog), others more (for example, the millipede and the bee). But all have an even number.[20]

Among the swimmers that are footless, some have fins, like the fishes. Among these, some have four fins, two above on the back, two below on the underneath parts (for 25
example, the gilthead and the sea bass), others two only, the ones that are very elongated and smooth (for example, the eel and the conger), others none at all (for example, the muraena and whichever others make use of the sea just as snakes make use of the earth; in fact, in liquid snakes swim in a similar way). Among the selachians, some have no fins (for example, the ones that are broad and long-tailed, like the ray and the stingray) 30
but swim by means of their broad bodies; but the fishing frog does have fins, as do those whose broadness does not thin out to a sharp edge. The swimmers that seem to have feet, like the soft-bodied animals, swim with these and with their fins, and do so faster in the direction of their cavity (for example, the cuttlefish, the large calamary, and the 35
octopus, but neither of the first two walks, as the octopus does). **490^{a}1**

The hard-skinned animals (for example, the crayfish) swim with their tail-parts, but faster in the direction of their tail, with the fins they have on it. And the water newt swims with its feet and tail-parts alike. The water newt has tail-parts that resemble those of the sheatfish, as small compared to great.

18. *GA* 752^{a}10–15.
19. Books 2 and 3.
20. *IA* 708^{a}21–^{b}13.

Among the flyers, some are feather-winged (for example, the eagle and the hawk), others membrane-winged (for example, the bee and the cockchafer), others skin-winged (for example, the flying fox and the bat). Those that are feather-winged are blooded, and the skin-winged ones likewise. The bloodless ones are skin-winged (for example, the insects). And the ones that are feather-winged or skin-winged are all two-footed or footless; for there are said to be certain snakes of this sort around Ethiopia. The feather-winged animal kind is called "bird," the two remaining kinds are not named by one name [each].

Among the flyers that are bloodless, some are coleopterans (for they have their wings in a wing case (*elutron*))—for example, the cockchafer and the dung beetle. Others have no wing case. And of these some are two-winged, others four-winged: four-winged are the ones that are of large size or have their sting in the rear; two-winged are the ones that are not of large size or have their sting in the front. Among the coleopterans, however, none has a sting. The two-winged ones have their stings in the front (for example, the fly, the horsefly, and the gnat).

All the bloodless animals are smaller in size than the blooded ones, with the exception of a few bloodless ones in the sea that are larger (for example, certain of the soft-bodied animals). And the largest of these kinds is in the hottest places, and in the sea rather than on land or in fresh water.

All animals that move around move by means of four or more points of movement. The blooded ones do so by means of four only (for example, the human being does so by means of two hands and two feet, the bird does so by means of two wings and two feet), while four-footed ones use four feet and fishes four fins. Those that have two fins or none at all (for example, the snakes), move by means of four points nonetheless; for their bends are at four points, or at two plus their fins. The bloodless ones that have many feet, whether they are winged or footed, move by means of more than four points of movement—for example, the so-called dayfly does so by means of four feet and four wings; for a special affection of this animal is not only what happens with regard to its lifespan (from which it gets its name) but also that it is both winged and four-footed.

All animals—four-footed as well as many-footed—move in a similar way; for they move with respect to a diagonal.[21] And while the other animals have two feet leading, the crab, alone among animals, has four.

1.6
Kinds of Animals; Simple Forms

The chief kinds of animals, into which the various animals are divided, are these: one for the birds; one for the fishes; another for cetaceans.[22] All these are blooded. Another kind is that of the hard-shelled animals, the so-called shellfish. Another,

21. 498[b]5–7, *IA* 712[a]24–27.
22. Reading κήτους.

that of the soft-shelled animals, which are not named by one name (for example, the crayfish and certain kinds of the crabs and the lobsters); another that of the soft-bodied animals (for example, the small calamary, the large calamary, and the cuttlefish); another that of the insects. All these are bloodless, and the ones that have feet, are many-footed; and some of the insects have wings as well.

Of the remaining animals, there are no chief kinds; for one form does not encompass many forms, but rather in some cases the form is simple and does not exhibit a difference (for example, the human being), other times they do exhibit a difference but the forms are nameless. For the wingless four-footed ones are all blooded, but some of them are live-bearing, others egg-laying. Not all live-bearing ones have hair, but all those that are egg-laying have hard-scales. And a hard-scale has a location similar to that of a soft-scale. Footless by nature, the snake kind is blooded, terrestrial, and hard-scaled. And all the other snakes are live-bearing, the viper alone being egg-laying. For not all live-bearing animals have hair; for certain fishes too are live-bearing. However, those that do have hair are all live-bearing. For we must also consider as a form of hair the sorts of spiny hair that hedgehogs and porcupines have; for these serve the purpose of hair, not of feet, like those of the sea urchins.

Of the four-footed and live-bearing animal kind, there are many forms, but they are without a [common] name, instead each one is spoken of in the way we say "the human being," "the lion," "the deer," "the horse," "the dog," and the others spoken of in this way; although there is actually[23] one single kind in the case of the so-called animals with long hair in their tails—for example, the horse, the ass, the mule, the ginnus, and the ones in Syria called "half-asses," which are called "half-asses" due to a similarity, though they are not unconditionally of the same form; for in fact they mate and generate from each other. That is also why it is necessary to get a theoretical grasp on [the various forms of animals] by grasping the nature of each of them separately.

What has just been said, then, is by way of an outline sketch, a foretaste of the things and affections on which we must get a theoretical grasp. But in what follows we will speak about them with exactness, in order to grasp, first, the differences and coincidental affections of all of them. After that, we should try to discover the causes. For this is the way to make the methodical inquiry in accord with nature, once the investigation of each is already in existence; for the things about which and from which there must be a demonstration become evident on the basis of these.

So first of all we must grasp the parts from which the animals are composed; for it is most of all and primarily with respect to these that the whole [animals] are differentiated, either by having some and not having others, or by their position, or by their order, or by the differences mentioned earlier, those of form, excess or deficiency, analogy, and contrariety among the affections.

First, then, we must grasp the parts of the human being; for just as each group of people evaluates currency in relation to the one best known to themselves, it is

23. Retaining καὶ.

the same way, of course, in other things. But of the animals the human being is of necessity the best known to us.

To perception the parts are not unclear. Nonetheless, for the sake of not neglecting the proper order of exposition, and of having reason together with perception, we must speak first of the instrumental parts, then of the uniform ones.

1.7
The Cranium

Among the parts into which the whole composite body is divided, the chief ones are these: the head, the neck, the thorax, the two arms, and the two legs (the cavity from the neck to the sex organs is called the "thorax").

Among the parts of the head, the one covered with hair is called the "cranium." Of it, the front part is the bregma, which is late in coming to be (for it is the last of the bones in the body to solidify), the back part is the occiput, and the part between the bregma and the occiput is the crown. Under the bregma is the brain, while the occiput is empty. The entire cranium is thin bone, round-shaped, and encompassed by fleshless skin. That of women has one circular suture, that of men for the most part has three sutures, joining together at one point, though a male head having no sutures at all has been observed. The part of the cranium called the "crown" is the middle line where the hair parts. In some cases this is double; for some people are double-crowned, not in virtue of the bone, but in virtue of the parting of their hair.

1.8
Forehead and Face

The part below the cranium, in the human being alone among the animals, is named "the face"; for we do not speak of the face of a fish or of a cow. The part of the face that is below the bregma and between the eyes is the forehead. Those in whom this is large are slower, those in whom it is small, quicker. Those in whom it is broad are excitable, those with a rounded one, contented.[24]

1.9
Eyebrows and Eyes (1)

Below the forehead are the eyebrows, which are naturally a pair. Straight ones are a sign of a soft character, those that bend in toward the nose, of a harsh one; those that

24. Reading εὔκολοι.

bend out toward the temples, of a mocking and self-deprecating one, those that are drawn in toward each other, of an envious one.

Below these are the eyes. They, when in accord with nature, are two. Of these, a part of each is an eyelid above and below. The hairs on their extremities are eyelashes. In the inside of the eye, the liquid part, the one with which we see, is the eye-jelly, and around this is the black, and outside it is the white. The common part of the upper and lower eyelids is a pair of corners, one near the nose, the other near the temples. If these are long, it is a sign of cynicism; if they have a fleshy part near the nostrils, resembling scallops,[25] it is a sign of wickedness.

All other kinds of animals—except the hard-shelled animals and any other kind of incomplete animals—have eyes; and all the live-bearing ones do, except the mole. But one might suppose that in a way it does have them, though not unconditionally. For unconditionally it neither sees nor has eyes that are clearly apparent. But when the skin is taken away, it has a space for the eyes, and has the black parts of the eyes in the place and in the space that is in accord with nature for the eyes when they are outside, suggesting that the eyes are deformed in the process of coming to be and the skin grows over them.

1.10
Eyes (2)

The white of the eye is for the most part similar in all animals, but the so-called black differs; for in some animals it is black, in others very blue, in others bluish-gray, in others greenish. This last is a sign of the best character and is best for sharpness of sight. **492^a1**

The human being is the one that alone—or most of all—among the animals has eyes of many colors. The others have one form. Although some horses have blue eyes.

Some eyes are large, others small, others intermediate in size. The intermediate ones are best. Also, some protrude, others are deep-set, others are intermediate. Among these, the deep-set ones are in all animals the most sharp-sighted; the intermediate a sign of the best character.

Also, they may tend to blink, to be staring, or be intermediate. The intermediate are a sign of the best character, and of the others, the second is a sign of shamelessness, the first of instability.

1.11
Ears, Nose, and Tongue

Further, there is a part of the head, incapable of breathing, through which an animal hears, the ear; for Alcmaeon is not speaking the truth in saying that the goats breathe

25. Reading οἱ κτένες (see *GA* 763^b12).

with their ears.[26] One part of the ear is nameless, the other is the lobe. The whole is composed of cartilage and flesh. The inside has a nature resembling that of spiral shells; the bone that is at the extremity is similar to the ear, and into this, as to the bottom of a vessel, the sound arrives. There is no duct from this to the brain, but there is one to the roof of the mouth, and a blood vessel from the brain extends to it. (The eyes too extend to the brain, and each is situated on a small blood vessel.)

Among the animals that have this part, the human being alone has an ear that is immobile. For of animals that have hearing, some have ears, others do not have them, but that they have the duct is evident—for example, the ones that are feathered or hard-scaled. But all the live-bearing ones—except for the seal, the dolphin, and the other such cetaceans—have ears (for the selachians too are live-bearing). But the human alone does not move them. The seal, then, has visible ducts by which it hears, while the dolphin, though it hears, has no ears. All the other animals move their ears.

The ears are situated on the same circumference as the eyes, and not, as in the case of some four-footed ones, higher up. And of the ears, some are smooth, some hairy, and some intermediate. The last are the best for hearing, but signify nothing about character. Also, they are large, small, or intermediate in size, very prominent, not prominent at all, or intermediate. The intermediate ones are a sign of the best
492b1 character, while large and prominent ones are a sign of a tendency to silly talk and babbling. The part between eye, ear, and crown is called the "temple."

Further, the part of the face that is a duct for breathing is the nose; for one both inhales and exhales through it, and sneezing, which is the expulsion of a gathered mass of breath, occurs through the nose. Among the breaths, sneezing alone is taken as something prophetic and sacred. At the same time, inhalation and exhalation occur in the chest, and it is impossible separately with the nostrils to inhale or exhale, because it is from the chest, along by the uvula, that inhalation and exhalation come, and not from any part of the head. And it is in fact possible to live without making use of this part.

Smelling does take place through this part: it is the perception of odor. The nostril (*muktêr*) is easily moved, unlike the ear, of which being immobile is a special affection. One part of it is a cartilaginous partition, the other an empty passage; for the nostril is cut in half. In the elephants the trunk[27] is long and strong, and it is used as a hand; for by means of this it draws things toward it, grasps them, and conveys nourishment, bold wet and dry, to its mouth, and it alone of the animals does so.

Further, there are two jaws. The front part is the chin, the back part is the cheek. All animals move the lower jaw, except the river crocodile, which moves the upper jaw only.

After the nose are two lips, fleshy and easily movable. The mouth is in the inside of the jaws and the lips. Its parts are the palate and the larynx.

26. Not in the extant fragments, B1–5 DK.
27. Literally, the nostril (*muktêr*).

The part that can perceive flavor is the tongue. Its perceptual modality is in its tip; if something is placed on the broad part, [the flavor] is less. The tongue too perceives all the things that other flesh can perceive (for example, hard, hot, cold) in any part of itself, just as it also perceives flavor. And it is broad, narrow, or intermediate. But the intermediate is the best and most perspicuous [in its discriminations]. Also, it is detached or tightly attached, as in those who mumble or lisp. The tongue is composed of flesh that is soft and spongy. The epiglottis is part of it.

Also, the part of the mouth that is divided in two is the tonsil, and the one that is multiply divided is the gum. These parts are fleshy. In the gums are the teeth, which are bony. **493^{a}1**

In the inside is another part, shaped like a hanging bunch of grapes, a pillar with prominent blood vessels. If when over moistened it gets enflamed, it is called a "bunch of grapes" and causes choking.

1.12
Neck, Thorax, Breasts, and Nipples

The neck is the part between the face and the thorax. Of this, the front part is the larynx, the back part, the gullet.[28] The cartilaginous and front part of this, through which passes the voice and the breath, is the windpipe. The fleshy part is the gullet. It is on the inside, in front of the spinal column. The back part of the neck is the *epomis*.

These, then, are the parts down to the thorax.

Among the parts of the thorax, some are at the front, others at the back. First, then, after the neck, in the front parts, is the chest with a pair of breasts. On these are a pair of nipples, through which in females the milk filters; and the breast is open-structured. Milk is produced in males as well [as females]. But in males the breast is dense, while in women it is spongy and full of ducts.

1.13
The Abdomen and Its (Male) Parts

After the thorax, in the front parts, is the abdomen, and its root is the navel. Below this root, forming a pair, is the flank. The single part under the navel is the lower abdomen (the extreme part of which is the pubic region). Above the navel is the upper abdomen. And the part common to the upper abdomen and the flank is the gut cavity.

A supporting girdle for the back parts is the pelvis (*osphus*). From this indeed its name derives; for it seems to be symmetrical in nature (*isophues*). Of the part for

28. Retaining τὸ δ' ὀπίσθιον στόμαχος.

evacuation, the one that is a sort of seat is the buttock, and the one in which the thigh turns is the hip socket.

A part special to the female is the uterus, while the sex organ is special to the male. It is external, situated at the end of the thorax, in two parts. [Of the one,] one part, the tip, is fleshy, always smooth and (one might almost say) of an equal size, and it is called the "glans," while the other, the skin around it is nameless. (If it is cut, it does not grow back together, any more than does the jaw or the eyelid.) Common to this part and to the glans is the tip of the foreskin. The remaining part is cartilaginous, grows large easily, and gets erect and flaccid in contrary ways.[29]

Below the penis are two testicles. The surrounding skin is called the "scrotum." The testicles are neither the same as flesh nor that far from flesh.

493b1 The way all the parts of this sort are will be spoken about with exactness in universal terms later on.[30]

1.14
Other Parts

The sex organ of a woman is contrary to that of males; for the part below the pubis is hollow and not, as with that of the male, projecting. And there is a urethra outside the uterus, which serves as a passage for the seed of the male, and is an outlet for the liquid residue in both [male and female].

The part common to the neck and the chest is the throat; the part common to the side, arm, and shoulder is the armpit; the part common to the thigh and lower abdomen is the groin. The part inside the thigh and the buttocks is the perineum; the part outside the thigh and the buttocks is the exterior junction of the buttocks and thighs.

The front parts of the thorax have now been talked about. The part behind the chest is the back.

1.15
Trunk and Limbs; Perceptual Parts

The parts of the back are the two shoulder blades, the spinal column, and below, on a level with the abdomen, is the loin. Common to the upper and lower part of the thorax are the ribs, eight on each side. (For about the so-called seven-ribbed Ligurians we have not yet heard anything reliable.)

The human being has an upper and lower part, front parts and back parts, right ones and left ones. The right sides and the left ones are pretty much similar in their

29. Secluding ἢ τοῖς λοφούροις.
30. 3.1 and *GA*.

parts, and the same in all respects, except that the left ones are weaker. The back parts are not like the front ones, nor the lower ones like the upper ones, except for the following points of resemblance: if the face is well supplied with flesh or poorly supplied with flesh, so are the lower parts of the lower abdomen; the legs correspond to the arms, and those that have short upper arms for the most part also have short thighs, and those with small feet, also have small hands.

Of the limbs, one pair are arms. The parts of the arm are the shoulder, the upper arm, the elbow, the forearm, and the hand. Those of the hand: the palm and the five fingers. Those of the finger: the one that bends is the knuckle, the unbendable one, the phalanx. The thumb is single-jointed, the other fingers two-jointed. The bend of both arm and finger is inward in all cases; the arm bends at the elbow. The inside of the hand is the palm, which is fleshy and divided by lines; in long-lived people by one or two going through the whole of it; in short-lived ones, by two, and they do not go through the whole of it. The joint at hand and arms is the wrist. The outer part of the hand, which is sinewy, is nameless.

Among the limbs, another pair are legs. Of the leg, the double-headed part is the thigh bone, the sliding part is the kneecap, the double-boned part, the shank. The front part of the shank is the shin, the back part is the calf, which is flesh that is sinewy and with large blood vessels. In some people (those that have large hips) it is drawn up toward the part behind the knee, in others it is drawn in the contrary direction. At the extremity of the shin is the ankle, a pair in each of the two legs. The many-boned part of the leg is the foot. The back part of the foot is the heel, and the front part is divided into five toes; the fleshy underneath part is the ball of the foot; the upper part at the back is sinewy and nameless. Of the toe, one part is the nail, the other the bend [or joint]. In all cases, the nail is at the extremity, and in all the toe is single-jointed. In those people the inside [or sole] of whose foot is thick and not arched, and so walk on the whole of it, are unscrupulous. The bend common to thigh and shank is the knee.

These, then, are the parts common to female and male.

The position that the parts have in relation to up and down, front and back, and right and left, might seem to be evident on the basis of perception as regards the external ones. Nonetheless, it must be spoken about due to the same cause as precisely the one due to which we also spoke about the previous parts: that is, so that the exposition be brought to an end in proper order, and that, by enumerating them, we are less likely to overlook those that are not the same way in the case of the other animals as in the case of human beings.

It is in the human being above all other animals that the upper parts and the lower parts are determined in relation to the places that are in accord with nature; for the upper parts and lower parts are positioned in relation to the upper and lower parts of the universe.[31] In the same way too the human being has the front parts and the

31. *DA* $416^{a}2$–5, *IA* $705^{a}32$–$^{b}2$.

back parts, the right parts and the left parts, in accord with nature. Among the other animals, some do not have them, while others, while they do have them, have them in a more indistinct way. In all cases the head is up above in relation to the animal's own body. But only the human being, as was said, when completed, has this part up above in relation to the universe.

494ᵇ1 After the head is the neck, then the chest and the back, the one in front, the other behind. And after these are the abdomen, the loin, the sex organ, and the haunch; then the thigh, the shank, and lastly the feet. Toward the front too is the bend the legs have, which is also the direction of their progression, as well as of the more mobile part of the foot and its bend; the heel is at the back and each of the two ankles correspond to the ears. On the sides, right and left, are the arms, which have their bend inward, so that the convexities of the bent legs and bent arms face each other most of all in the human being.

The perceptual modalities and the perceptual organs—the eyes, the nostrils, and the tongue—all face in the same direction and are had at the front. But the capacity of hearing and its perceptual organ, the ears, are at the side, though on the same circumference as the eyes. Among the animals, the eyes are least far apart in the human being, for its size. And the human being has the most exact perception of touch, and the second most of taste. But in the others it falls short of many animals.

1.16
The Internal Parts

The parts visible on the outside surface of the body, then, are arranged in this way, and, as was said, they are mostly distinguished by name and are known through intimacy with them. The inner parts, however, are the contrary. For the inner parts of human beings are especially unknown, so that we must refer our investigation to those of the other animals that have a nature that is much the same.

First, then, situated in the head, and having a position in the front, is the brain. And it is likewise too with whatever other animals have this part. And all the ones that have blood have it, and furthermore so do the soft-bodied animals. But, among animals of the same size, it is the human being that has the largest and wettest brain. Two membranes encompass it, the one around the bone is stronger, the one around the brain itself less strong than the former. In all animals the brain has a pair of parts. Behind this, at the extremity, is what is called the "cerebellum," which has a shape that to both touch and sight is distinct.

The back of the head is empty and hollow in all animals, in keeping with the size **495ª1** that each has. For some have a large head, but the part of the face below is comparatively small (the ones that are round-faced), while others have a small head and long jaws (for example, all of the kind with long hair in their tails).

The brain is bloodless in all animals, that is, it has no blood vessels in it at all, and is naturally cold to the touch. It has at its center in most animals a small hollow. The meninx around the brain has large blood vessels (the meninx is the skin-like membrane that encompasses the brain). Above the brain is the thinnest and weakest bone in the head, which is called the "bregma."

From the eye three ducts lead to the brain, the largest and the middle one to the cerebellum, the smallest to the brain itself; the smallest is the one nearest the nostril. The largest ones are parallel and do not meet, but the middle ones do meet (this is especially clear in the case of the fishes); for these are also nearer the brain than the large ones are. The smallest ones are farthest apart from each other and do not meet.

In the inside of the neck is the so-called esophagus—which gets its derived name [*stomachos* ("gullet")] from its length (*makros*) and narrowness (*stenos*)—and the windpipe. The windpipe is situated in a position in front of the esophagus, in all animals that have it; and the ones that have it are precisely all the ones that have a lung. The windpipe is cartilaginous in nature and has little blood, but it is encompassed by many small thin blood vessels. It is situated, in its upper part, near the mouth, below the aperture from the nostrils to the mouth, where too, when people are drinking and they inhale some of their drink, it advances from the mouth out through the nostrils. Between the two apertures is what is the so-called epiglottis, which is capable of being folded over the aperture that leads to the mouth. The extremity of the tongue is attached to it. At the other end the windpipe comes down to the middle of the lung, then from there it divides, going to each of the two parts of the lung. For the lung tends to have two parts in all the animals that have it. But in the live-bearing animals the division is not evident to the same degree, and is least so in the human being. And it is not multi-divided in the human being, as in some of the live-bearing **$495^{b}1$** animals, nor is it smooth, but rather exhibits unevenness.

In the egg-laying animals (for example, the birds and in those four-footed ones that are egg-laying), the two parts are quite separate from each other, so that they seem to have two lungs. And from the single windpipe there are two parts, one extending to each of the two parts of the lung. It is also attached to the great blood vessel and to the so-called aorta.

When the windpipe is inflated, the breath is distributed to the hollow parts of the lung. These have cartilaginous partitions that meet at an acute angle. And from the partitions there are apertures going through the entirety of the lung, which are always so distributed that smaller ones follow larger ones.

The heart too is attached to the windpipe, by fatty, cartilaginous, and fibrous ligatures; and at the point of attachment, it is hollow. And when the windpipe is inflated, though in some animals this is not made visible, in the larger animals it is clear that the breath enters into it.

The windpipe, then, has this mode of arrangement, and only takes in and emits breath, but takes in nothing else, whether dry or wet, or else produces pain, until one coughs up what has gone down it.

The gullet is attached at the top to the mouth, contiguous to the windpipe, and conjoined with the spinal column and the windpipe by membranous ligatures, ending, by way of the diaphragm, in the stomach. Its nature is fleshy and it has elasticity both in length and in breadth.

The stomach of the human being is similar to that of the dog; for it is not much larger than the intestine, but rather is like a sort of intestine that has a certain size. Next is the simple intestine, which spirals; next the intestine having breadth.[32] The lower part of the bowel[33] is similar to that of the pig; for it is large, and the part going from it to the fundament is thick and short. The omentum[34] is attached to the middle of the stomach, and has the nature of a fatty membrane, just as in the other single-stomached animals that have two rows of teeth.

Above the intestines is the mesentery. This too is membranous and large and becomes fatty. It is attached to the great blood vessel and to the aorta, and throughout it are many blood vessels densely packed together, which extend to the position of the
496ᵃ1 intestines, starting above and continuing to down below.

Things having to do with the gullet, the windpipe, and the stomach, then, stand this way.

1.17
Heart and Viscera

The heart has three cavities, is situated above the lung at the point where the windpipe divides into two, and it has a membrane that is fatty and dense where it is attached to the great blood vessel and the aorta. And it is situated with its pointy end on the aorta. And its pointy end is situated toward the chest, alike in all animals that have a chest. And in all animals, alike in both those that have and those that do not have this part, the heart has its pointy end turned toward the front, though this may often escape notice because of its migration during dissection. The rounded end of it is at the top. The pointy end is fleshy in most cases and dense, and there are sinews present in its cavities. While it is situated in the middle of the chest in the other animals (the ones that have a chest), in human beings its position is more in the left, leaning a little away from the division of the breasts toward the right breast, at the upper part of the chest.

Also, the heart is not large, and its form as a whole is not elongated but roundish, except for the extremity where it comes to a point. It has three cavities, as was just said, the largest is on the right, the smallest on the left, and the medium-sized one in the middle. All of them, even the two smaller ones, are connected to the lung by

32. Reading εἶτα ἕντερον εὖρος ἔχον.
33. Or "stomach."
34. *PA* 677ᵇ17–21.

passages,[35] though quite visibly so [only] with regard to one of the cavities. Below, at the point of attachment, from the largest cavity, the heart is attached to the great blood vessel, near where the mesentery is, and from the middle one to the aorta.

Ducts also lead to the lung from the heart, and divide in two just as the windpipe does, following over all the lung the paths of those from the windpipe. Uppermost are the ones from the heart. There is no common duct, but because of their contact they take in the breath and transmit it to the heart; for one of the ducts leads to the right cavity, the other to the left.

About the great blood vessel and the aorta by themselves we will speak in common later on.[36]

Among the parts present in the animals that both have a lung and are internally and externally live-bearing, the lung has the most blood; for the entirety of it is spongy, and along the bronchial passages, ducts bring the blood of the great blood vessel. But those who consider the lung to be empty are entirely deceived, because of looking at ones that have been removed from animals during dissections, from which the blood has immediately all withdrawn at once. **496^{b}1**

Among the other viscera, the heart alone has blood. And the lung has it not within itself but in its blood vessels, while the heart has it within itself; for it has blood in each of its cavities, and the finest-grained is in the middle one.

Below the lung is the thoracic diaphragm, the so-called midriffs, which are attached to the ribs, the upper abdomen, and the spinal column, and in the middle has something thin and membranous. It has blood vessels extending through it. The midriffs of the human being are thick in proportion to his body.

Below the diaphragm on the right side the liver is situated, and on the left the spleen, and likewise in all animals that have these parts in accord with nature and not in a monstrous way; for cases have been observed in certain four-footed animals in which the positions are exchanged. They are connected to the stomach through the omentum.

In appearance the spleen of the human being is narrow and long, similar to that of the pig. And the liver for the most part, and in most animals, has a gallbladder, but in some animals it does not. The liver of the human being is roundish, similar to that of the cow. (This absence of the gallbladder is also met with in sacrificial animals—for example, in a certain place in Chalcis in Euboea the sheep do not have a gallbladder, while in Naxos pretty much all the four-footed animals have one so large that strangers when offering sacrifice get quite a shock, thinking the [large gallbladder] to be a sign special to themselves, not that this is the animal's nature.)

The liver is attached to the great blood vessel, but has no communication with the aorta; for the blood vessel from the great blood vessel traverses the liver at a point

35. Reading ἁπάσας δ' ἔχει, καὶ τὰς δύο μικράς, εἰς τὸν πλεύμονα τετρημένας.
36. *HA* 3.3–4, *PA* 3.5.

called the liver's "portals." The spleen too is connected to the great blood vessel alone; for a blood vessel extends from it to the spleen.

After these are the kidneys, situated near the spinal column, and similar in nature to those in cows. The right one is higher up in all the animals that have kidneys. And the right one also has less fat than the left and is drier. And it is this way in all the other animals too. Ducts lead to them from the great blood vessel and from the aorta, though not into the cavity. For the kidneys have a cavity in the middle, some a larger one, some a smaller one, except for those of the seal; for these are similar to those of cows, but are most solid of all.

The ducts extending to the kidneys lose themselves in the body of the kidneys. A sign that they do not penetrate [the cavity] is that the kidneys do not have blood, nor does it coagulate in them. And they have a small cavity, as was just said. And from the cavity of the kidneys two sturdy ducts lead into the bladder. Others come from the aorta that are strong and continuous. At the middle of each of the two kidneys is attached a hollow and sinewy blood vessel that extends along the spinal column itself through the narrow regions, then they disappear into either haunch, and become clearly visible again in extending to the haunch. These branches of the small blood vessels reach down in due course to the bladder.

For the bladder is situated at the extremity, having an attachment there via the ducts that extend from the kidneys along the stalk that extends to the urethra, and pretty much all around it is fastened by thin sinewy membranes that are in a certain way much the same as the thoracic diaphragm. In the human being, the bladder has moderate size.

To the stalk of the bladder is attached the penis; the outermost aperture encounters at the same point another one [of two], which is smaller and lower down. One of the apertures leads to the testicles, the other to the bladder. [The penis] is sinewy and cartilaginous. To this, in males, the testicles are attached. The way they have these will be determined in the common accounts.[37]

In the female too all the parts are naturally the same way; for it does not differ in the internal ones, except for the uterus, the visual appearance of which one must observe with the help of the diagrams in the *Dissections*. Its position is over the bowel. And over the uterus is the bladder. But the uterus too in all animals in common must be spoken about in what follows; for it is neither similar in all of them nor is it possessed in a similar way.

The parts, then, of the human being, both the internal ones and the external ones, are these and of this sort, and it has them in this way.

37. The reference is presumably to *HA* 3.1, where the accounts are "common" because dealing with the testicles in all animals that have them, not (as here) just in human beings.

BOOK 2

2.1
Differences between the Animals, Their Parts, and Their Movements

Among the parts of the other animals, some are common to all, as was said previously,[38] others to certain kinds. And these are the same or different from each other in the way that has already often been stated. For in the case of pretty much all the animals that are in distinct kinds, the majority of their parts are distinct in form too, and some are undifferentiated by analogy only, but distinct in kind, while others are the same in kind but distinct in form. But many parts belong to certain animals and not to others.

Thus, the live-bearing four-footed animals all have a head, a neck, and all the parts that are in the head, but each of these parts differs with respect to shape. The lion, for example, has a neck consisting of one bone, and has no vertebrae; but, when it is opened up, all its internal parts are like those of a dog.

The live-bearing four-footed animals also have front legs in place of arms. But, though this is the case for all four-footed animals, the multi-split-footed ones have their front legs most analogous to hands—for they are used as hands for many things (and the ones on the left are less differentiated [from the right] than in human beings)—with the exception of the elephant. This latter has parts around the toes that are more without joints, and its front legs are much larger; it has five toes and on its hind legs has short ankles. Its trunk, however, is of such a sort and of such a size that it has it in place of hands; for with this instrument, it drinks and eats by putting things into its mouth, and hands them up to the elephant-driver on its back. It even pulls up trees with it and, when walking through water, blows it upward with this. It coils at its tip, but does not bend; for it is cartilaginous.

But among the various animals only a human being can actually become ambidextrous.[39]

All animals have a part analogous to the human chest, but not similar to it; for the human chest is broad, while those of the others are narrow. And none have breasts in the front except the human being; the elephant does have two breasts, but they are not on the chest, but near the chest. **498^{a}1**

And all animals, with the exception of the elephant, have the bends both of the front limbs and the back limbs set opposite to each other and to the bends of the human being. For in the live-bearing four-footed animals the front limbs bend forward and the back ones bend backward, and have the concavities of the curves turned toward each other. The elephant does not behave as some people said, but settles

38. 1.1.
39. *NE* $1134^{b}34$, †*MM* $1194^{b}33$–39, *Pol.* $1274^{b}13$.

down and bends its legs, except that it cannot, because of its weight, do so on both sides at the same time, but reclines either on its right side or on its left, and goes to sleep in this position. On the other hand, it bends its back legs precisely the way a human being does.

In the case of the egg-laying animals, like the crocodile, the lizard, and all the animals of this sort, both pairs of legs, both the front ones and the back ones, bend forward, with a slight inclination to the side. It is likewise in the case of the various many-footed animals, except that the legs between the extreme ones always play a double game,[40] and so bend more sideways. In the case of the human being, by contrast, the bends of both pairs of limbs are set toward the same point, that is, in contrary directions; for it bends the arms toward the back (except that there is a slight turning inward), and the legs toward the front. No animal at all bends both its front legs and its back legs backward. But in the case of all animals the bend of the shoulders is in a contrary way to that of the elbows or the joints of the front legs, and the bend of the hips to that of the knees of the back legs, so that, since the human being bends his limbs in the contrary way to most[41] animals, those that possess joints of this sort[42] bend them in the contrary way too.

The bird too has bends that are much the same as those of the four-footed animals; for, though it is two-footed, it bends its legs backward, and in place of arms (that is, front limbs), it has wings, of which the bend is forward.

As for the seal, it is a sort of deformed four-footed animal;[43] for it has feet immediately after the shoulder blade that are similar to hands, like those of the bear; for each has five toes, and each of the toes has three bends and a nail that is not large. The back feet also have five toes, and have bends and nails similar to the front feet, but in shape they are much the same as the tails of fishes.

The movements of animals, both of four-footed ones and of many-footed ones, are diagonal, and they stand still in the same way; and in all of them the starting-point [of movement] is from the feet on the right. But the lion and the two sorts of camel, the Bactrian ones and the Arabian ones, walk laterally.[44] And lateral walking is when the right foot does not go before the left, but instead follows along with it.

Whatever parts the human being has in the front, the four-footed animals have below, on the underneath parts, and the ones it has behind, they have on their back parts. Further, most of them have a tail; for even the seal has a small one, similar to that of the deer. (About the apelike animals we will make determinations later.[45])

All the live-bearing four-footed animals are (one might almost say) hairy, not like the human being, who is sparse-haired and short-haired except for his head—though

40. I.e., they share in the bends of both the front and the back legs.
41. Reading πολλοῖς.
42. Reading τὰ τοιαῦτα.
43. *PA* 657a23–25.
44. 629b14.
45. 2.8.

among the animals it has the hairiest head.[46] Further, among the various hairy animals, the back is hairier, but their underneath parts are either altogether hairless or less hairy. With the human being it is the contrary. The human being also has eyelashes on both lids, and has hair in the armpits and the pubic region, while none of the other animals has it in either of the latter places, or has a lower eyelash—though some animals have some sparse hair growing under the eyelid.

Among the four-footed animals themselves that have hair, some are hairy all over the body, like the pig, the bear, and the dog; others are especially and similarly hairy all around the neck—for example, those that have a mane, like the lion; others are especially hairy on the upper surface of the neck from the head as far as the withers—for example, those that have a crested mane, like the horse, the mule, and—among the wild horned animals—the bison.

The so-called horse deer[47] also has a mane on its withers, as does the beast named the *pardion*;[48] each of the two has a mane of fine hair extending from the head to the withers; but special to the horse deer is having a beard by the larynx. Both these animals are horned and split-footed, but the female horse deer does not have horns. **499^{a}1** The size of this animal resembles that of the deer. The horse deer live in Arachotae, precisely where the wild cattle also live. (Wild cattle differ from tame ones in very much the way wild pigs differ from tame ones, for they are black, strong in form, with a hooked muzzle, and with horns lying more over the back.) The horns of the horse deer are much the same as those of the gazelle.

The elephant is the least hairy of the four-footed animals.

The hairiness or hairlessness of the tails follow along with those of the body in whatever animals have a long tail; for some have an altogether small one.

Camels[49] have a special part in comparison to the other four-footed animals, the so-called hump on the back. But the Bactrian camels differ from the Arabian ones; for the former has two humps, the latter only one—although it has another hump below like the one above, on which, when it kneels down, the rest of the body is supported. The camel has four nipples like the cow, a tail like that of an ass, and its sex organ is at the back. It has one knee on each leg, which does not have several bends, as some people say,[50] but appears to because of the lower part[51] of its stomach. It has a knucklebone[52] like that of a cow, but meagre and small for the animal's size. It is split-footed and does not have two rows of teeth. It is split-footed in the following way: there is a small split that starts from the back and goes up to the second joint of the toes; in the front there is a small split as far as the first joint of the toes up to the

52. *PA* 654^{b}20–23.

extremities of the four feet; and there is something in the middle of splits as in the case of geese. The foot is fleshy underneath, like those of the bear; that is why the ones going to war have leather boots [put on] when their feet get sore.

All the four-footed animals have legs that are bony, sinewy, and fleshless. And, in general, it is so for all other animals too, except the human being. Further, they lack buttocks; and indeed the birds have this affection to a yet higher degree. But with the human being it is the contrary; for the parts of the body that are pretty much the most fleshy are the buttocks, thighs, and shanks. For the so-called calves in the shanks are fleshy.

Among the blooded live-bearing four-footed animals, some have multi-split feet, like the hands and feet of the human being (for some have many toes—for example, the lion, the dog, and the leopard); some have split feet with hooves in place of nails, like the sheep, the goat, the deer, and the hippopotamus; and some have unsplit feet—for example, the solid-hoofed ones, like the horse and the mule. The pig kind plays a double game; for there are solid-hoofed pigs in Illyria, Paeonia, and elsewhere. The cloven-hoofed animals have two splits at the back; but in the solid-hoofed ones this part is continuous.

Again, some animals are horned, others hornless. Most of the horned ones have, in accord with their nature, cloven hooves—for example, the cow, the deer, and the goat; a solid-hoofed two-horned one has never been seen. But there are a few one-horned solid-hoofed ones—for example, the Indian ass.[53] The oryx[54] is one-horned and cloven-hoofed.

The Indian ass is also the only solid-hoofed animal with a knucklebone; for the pig, as was said previously,[55] plays a double game, which is why it does not have a well-formed knucklebone. Many of the cloven-hoofed animals have a knucklebone. No multi-split-footed animal has been seen to have this sort of knucklebone, any more than a human being; but the lynx has something like a hemi-knucklebone, and the lion has one very much like the labyrinthine shape they use in molding.[56] All those that have a knucklebone have it in the back legs. The knucklebone is set upright in the joint, with the upper part outside and the underneath part inside; the sides called "Coan" are inside, facing each other, those called "Chian" are outside, and the "horns" are on the top.[57] The position, then, of the knucklebones in the case of all the animals that have them is this way.

Some animals have, at the same time, cloven hooves, a mane, and two horns bent toward each other—for example, the bison that live around Paeonia and Maedica. All the horned animals are four-footed, except for one said to have horns metaphorically,

53. The Indian rhinoceros.
54. Probably a sort of antelope (but not one-horned).
55. 499ᵇ12.
56. An *astragalos* is both a knucklebone and a sort of molding on the capital of an Ionic column.
57. The terms come from the game of knucklebones.

by a figure of speech—as the snakes around Thebes are said to be by the Egyptians, when what they have is a protuberance that occasions the description. Among the ones having horns, only the deer's are solid throughout, others are hollow up to a point, while the extremity is solid. The hollow part more naturally stems from the skin, although the solid part fastened around this stems from the bones—for example, the horns of cows. The deer alone sheds its horns each year, starting from its second year, and then grows them again. The others have them in a continuous way, unless they are docked by force.

Further, the breasts and the instruments used for mating belong in contrary ways in the other animals both in relation to themselves and in relation to the human being. For some have their breasts in the front, on the chest or near the chest, and have two breasts and two nipples, like a human being and an elephant, as was said previously.[58] For in fact the elephant has the two breasts near the axillae, and the female has altogether small breasts and not ones in proportion to the body, so that from the side they cannot be seen at all. The males also have altogether small breasts like the females. The female bear has four. Some animals have two breasts, but near the thighs, and two nipples, like the sheep; others have four nipples, like the cow. Some have breasts neither on the chest nor near the thighs, but on the abdomen—for example, the dog and the pig—and have many of them, but not all of equal size. While others have numerous ones, the female leopard has four on the abdomen, and the lioness two on the abdomen. The camel also has two breasts and four nipples, like the cow. Among the solid-hoofed animals, the males do not have breasts, except for those that bear a likeness to the mother, which is precisely what happens in the case of horses.[59]

Some males have their sex organs external (for example, the human being, the horse, and many others), others internal (for example, the dolphin). And among those that have them externally, some have them in the front (like the ones mentioned), and, among these, some have both the sex organ and the testicles detached (for example, the human being), others have the sex organ and the testicles close to the abdomen, some more, some less detached; for this part is not equally detached in the boar and the horse. The elephant has a sex organ like that of the horse, but small and not in proportion to the body, and the testicles are not visible externally, but are inside near the kidneys; that is why in mating it gets off quickly. The female has the sex organ in the place where the udder is in sheep. When she is getting ready to mate, she draws it back and turns it toward the external place, so that mating is easier for the male; and the sex organ opens wide. These are the ways, then, that the sex organs are in most animals.

Some animals urinate backward—for example, the lynx, the lion, the camel, and the hare. Male animals, as was said,[60] do so in contrary ways from each other, but all

58. $497^{b}34$–$498^{a}2$.
59. *PA* $688^{b}33$.
60. *PA* $689^{a}31$–35.

the females urinate backward; for even the female elephant, though having[61] the sex organs below the thighs, also does so just like the others.

Among sex organs there is much difference. For some animals have a sex organ that is cartilaginous and fleshy, like the human being; and the fleshy part does not become inflated, but the cartilaginous part can increase in size. In some, it is sinewy, as in the camel and the deer, while in others it is bony, as in the fox, the wolf, the marten, and the weasel; for in fact the weasel has a bone for a sex organ.

In addition to these things, when the human being is completely grown, the upper part is smaller than the lower, while with the other blooded animals it is the contrary. By the "upper" we mean the region from the head to the part for the outlet of the residue; by "lower" we mean the rest of the body from there. In footed animals, then, the back leg is lower in relation to their [overall] magnitude, and in footless ones, their tails, caudal appendages, and parts of this sort.

When they are completely grown, then, animals are like this, but in the process of growing they differ; for the human being, when young, has the upper part larger than the lower, but as he grows, he changes to the contrary (that is also why he alone
501ᵃ1 does not make the same progressive movement when young as when completely grown, but in first infancy crawls on all fours). Some animals exhibit the same relative proportions as they grow—for example, the dog. Some animals at first have the upper part smaller and the lower one larger, but as they grow the upper one becomes greater—for example, those with long hair in their tails;[62] for in none of these does the part between the hoof and the haunch become larger.

Again, as regards the teeth, there are many differences between the various animals both in relation to each other and in relation to the human being. For all blooded live-bearing four-footed animals have teeth. But, first, some have two rows of teeth and some do not have two rows of teeth. For those that are horned do not have two rows of teeth; for they do not have their front teeth in the upper jaw. And there are some that do not have two rows of teeth and are hornless—for example, the camel. And some have tusks (for example, the boar), while others do not. Further, some of them are sawtoothed (for example, the lion, the leopard, and the dog), while others have non-interlocking teeth (for example, the horse and the cow); for the sawtoothed ones are those whose sharp teeth interlock. No animal has both tusks and horns at the same time; nor does any sawtoothed one have either of these. Most animals have their front teeth that sharp, and their inner ones broad. The seal is sawtoothed as regards all its teeth, because it overlaps with the fish kind; for pretty much all the fishes are sawtoothed.

No animal of these kinds has double rows of teeth. But there is one, if we are to trust Ctesias; for he says that a beast in India, the name of which is "martichoras," has a triple row of teeth in both jaws; that it is as large as a lion, is equally hairy, and has similar feet; that its face and ears are like a human being's, its eyes blue, and its color

61. Reading καίπερ ἔχων.
62. 491ᵃ1.

vermillion; that its tail is like that of the terrestrial scorpion; that it has a sting in the tail, with spines that it can shoot off like javelins; that its voice sounds at the same time like a pipe and a trumpet; that it can run no less fast than a deer; and that it is savage and man-eating. **$501^{b}1$**

The human being sheds its teeth, and other animals shed them too—for example, the horse, the mule, and the ass. The human being sheds its front teeth, but no animal sheds its molars. The pig sheds none of its teeth at all.

2.2
The Teeth of Dogs

About dogs there are disputes: some think that they shed absolutely none of their teeth, some that they shed only the canines; yet it is seen that they do shed them, just as the human being does, but this escapes notice because they do not shed them until equivalent ones grow up as a substitute inside. It is likely that something similar also occurs in the case of the other wild beasts, since they are said, at any rate, to shed only the canine teeth. People distinguish young dogs from old ones by their teeth; for the young ones have white sharp teeth, while the old have black blunt ones.

2.3
The Teeth of Horses

In the case of horses too the contrary occurs to what occurs in the other animals; for as the other animals become older they have blacker teeth, while the horse has whiter ones.

The so-called canines mark the boundary between the sharp teeth and the broad ones, participating in the shape of both; for they are broad below and sharp above.

Males have more teeth than females both in human beings and in sheep, goats, and pigs. In the case of the others, the issue has not yet been looked into. But the ones that have more teeth are for the most part longer-lived, while those with fewer and more widely spaced teeth are for the most part shorter-lived.

2.4
Wisdom Teeth

In human beings, the last teeth to grow are molars, so-called wisdom teeth, which do so around the age of twenty both in men and in women. In women of eighty years, cases have been observed of molars coming in at the extremities [of the jaws], causing pain while growing in, and likewise in the case of men. This occurs in those whose wisdom teeth did not grow at the proper age.

2.5
The Teeth of Elephants

30 The elephant has four teeth on each side with which it masticates its nourishment (grinding it like coarse barley meal), and separate from these it has two others—the great ones.[63] The male has these large and curved upward, the female has them small
502a1 and going contrary to those of the males; for the teeth look downward. The elephant has teeth right from birth, however, the great ones are invisible at first.

2.6
The Tongue of Elephants

The elephant has a very small tongue and placed [well] inside, so that it takes work to see it.

2.7
The Size of Mouths

5 The animals also differ in the size of the mouth. For some have mouths that open wide (like the dog, the lion, and all the sawtoothed animals), others have small mouths (like the human being), others have intermediate-sized ones (for example, the pig kind).

10 {The Egyptian hippopotamus has a mane like a horse, is cloven-hoofed like a cow, and is snub-nosed. It has a knucklebone like the split-footed animals, tusks that are barely apparent, the tail of a pig, and the voice of a horse. Its size is the size of an ass. The coarseness of its skin is such that spear shafts are made from it. Its internal parts
15 are like those of the horse and the ass.}[64]

2.8
The Apes (1)

Some of the animals have a nature that plays a double game with that of the human being and that of the four-footed animals—for example, the apes, the monkeys, and the baboons. The monkey is an ape with a tail. The baboons, for their part, have the same shape as the monkeys, except that they are bigger and stronger and have faces
20 more like a dog's; further, they are more savage in character and have teeth that are more like a dog's and stronger.

63. I.e., the tusks.
64. The paragraph is closely similar to Herodotus 2.71 and may be an interpolation.

The apes are hairy on the back, as being four-footed, and on the underneath parts, as being like human beings (for human beings have this in the contrary way to the four-footed animals, as was said previously[65]), except that the hair is coarse, and that the apes are very hairy on both sides. The face has many similarities to that of the human being; for it has nostrils, ears, and teeth—both front and molars—that are much the same as those of the human being. Further, while other four-footed animals do not have lashes on both eyelids, the ape does, though they are very fine and altogether small, especially the lower ones; for in fact the other four-footed animals do not have these.

Further, the ape has on its chest two nipples on small breasts. It has arms like the human being, except hairy, and it bends these and its legs as the human being does, with the convexities of both limbs facing each other.[66] In addition, it has hands, fingers, and nails like those of the human being, except that all these tend to be more beastlike. Its feet are special to it; for they are like large hands, and the toes are like fingers, the middle one being longest; and the bottom of the foot is like a hand, except that it is longer than the bottom of the hand, and stretches toward the extremities, just like a palm; it is harder at the end, and in a poor and indistinct way imitates the heel. It uses its feet in two ways, both as hands and as feet, and bends them like hands. Its upper arm and thigh are short in relation to the lower arm and shank. It does not have a protruding navel, but something hard in the navel's place. It has a much larger upper part than a lower,[67] like the four-footed animals; for the ratio is pretty much five to three. And because of these things, and because it has feet that are like hands, and are composed, as it were, of hand and foot (of foot as regards the extremity of the heel, of hand as regards the other parts, for even the toes have a so-called palm), it spends most of its time on all fours rather than upright. It has neither buttocks (as being four-footed) nor tail (as being two-footed), except for an utterly small one, just enough for a sign of one. The female has a sex organ like that of a woman, while the male has one that is more like that of a dog than that of the human being.

2.9
The Apes (2)

The monkeys, as was said previously,[68] have a tail. But all the animals of this sort have internal parts, when dissected, that are like those of the human being.

These, then, are the ways the parts are in the externally live-bearing animals.

65. $498^{b}19–21$.
66. $498^{a}19–22$.
67. $500^{b}28–30$.
68. $502^{a}18$.

2.10
The Blooded Egg-Laying Four-Footed Animals

The four-footed animals that are egg-laying and blooded (and no terrestrial blooded animal is egg-laying unless it is four-footed or footless) have a head, a neck, a back, the back and underneath parts of the body, front and back legs, and an analog of the chest, just as the live-bearing four-footed ones do, and most have a long tail, while a few a short one. And all animals of this sort are many-toed and multi-split-footed. In addition, they all have perceptual organs and a tongue, except for the Egyptian **503a1** crocodile. (This one is much the same way as that of certain fishes; for in general the fishes have a tongue that is prickly and not detached, while some have this place altogether smooth and undifferentiated unless one opens their mouth very wide [to look inside].)

All the animals of this sort have no ears, but only the duct for hearing, no breasts, no sex organ, no evident external testicles, but internal, and no hair; but all are hard-scaled. Further, they are all sawtoothed.

River crocodiles have the eyes of a pig, but large teeth, and tusks, strong nails, and a skin that is impermeable and hard-scaled. They see poorly in water, but with great acuity outside it. Mostly, they spend the day on the land and the night in the water; for it is warmer than the open air.

2.11
The Chameleon

The chameleon has a body shaped generally like a lizard's, but the ribs come down and meet near the lower abdomen, as with the fishes, and the spinal column sticks up as with the fishes. The face is very like that of the baboon. It has a very long tail that comes to a fine point and is coiled up to a great extent, like a leather thong. It stands higher off the ground than the lizards, but it has a bend of the legs like that of the lizards. Each of its feet is split into two parts, which have a relation to each other corresponding to the one our thumb has to the rest of the hand. And each of these parts is divided for a short distance into a certain number of toes: on the front feet, the inside part is divided into three and the outside part into two, while on the back feet, the inside part is divided into two and the outside into three. The fingers have nails like those of the crook-taloned birds.

Its body is rough all over, like that of the crocodile. It has eyes situated in a hollow recess that are very large, round, and surrounded by skin that is like the rest of the body. In the middles of these small apertures have been left for vision, through which it sees. This aperture is never covered with skin. It turns its eye **503b1** circularly, changes the direction of its vision toward every place, and in this way sees what it wishes.

The change of its color occurs when it becomes inflated with air. It has a color that is black, not far removed from that of the crocodile, yellow like the lizards, black-spotted like the leopards. This sort of change occurs over its whole body; for the eyes also change in a similar way along with the rest of the body, also the tail. Its movement is exceedingly sluggish, like that of the turtles. When dying, it becomes yellow, and its color is like this once it is dead.

The gullet and the windpipe are situated like those of the lizards, but there is no flesh anywhere, except for a few bits of flesh on the head, jaws, and around the extremity where the tail grows. It has blood only around the heart, the eyes, the place above the heart, and in the small blood vessels extending from these; but even there it is in altogether short supply.

The brain is situated slightly above the eyes, but is continuous with them. When the outer skin of the eyes is removed, they have something that surrounds them and shines through them, like a thin copper ring.

Over pretty much all of its body membranes extend that are both numerous and strong, far more so than those in the rest of the animals. And it is even active with its breath for a long time after being cut open along its whole length, there being still a very slight movement in it around the heart, and though the contraction is particularly in the parts around the ribs, nonetheless it is also in the rest of the parts of the body.

It has no visible spleen.

It goes into hiding like the lizards.

2.12
The Birds

The birds too have some parts in a similar way to the animals that have been spoken about; for all of them have a head, a neck, a back, underneath parts, and an analog of the chest. They have two legs—[in this respect] are the animals most like a human being, except that they bend them backward like the four-footed animals, as was said previously.[69] They have no front feet or hands, but wings—a part special to them in comparison to the other animals. Further, their haunch is long, like a thigh, and attached as far as the middle of the abdomen, so that when divided off it seems to **$504^{a}1$** be a thigh, although the thigh, which is intermediate between it and the shank, is a distinct part. Among the birds, the crook-taloned ones have the largest thighs and the strongest chest than the others.

All the birds have numerous nails; further, all are in a way multi-split-footed; for in most the toes are divided, while the swimmers, though web-footed, have their toes articulated and separated. Those that fly high in the air all have four toes; for most

69. $498^{a}27$–30.

have three in the front and one situated behind in place of a heel; but a few have two in front and two behind—for example, the so-called wryneck.[70] It is slightly larger than the chaffinch, and variegated in appearance. Special to it are the features having to do with its toes and with its tongue, which is like that of the snake; for it can extend it for a length of four finger-widths and then draw it back into itself again. Further, it can turn its head backward while keeping the rest of its body unmoved, like the snake. It has large nails, though in nature they are like those of the green woodpecker.[71] Its voice is a shrill cry.

Birds have a mouth, but it is a special one; for they have neither lips nor teeth, but a beak, and neither ears nor noses, but the ducts of these perceptual modalities: those for the nostrils in the beak, and those for hearing in the head. All of them have two eyes like the other animals, without lashes. The heavy birds[72] close their eyes with the lower eyelid, and all birds blink with a skin coming from the inner corner, while birds of the owl kind close their eyes with the upper eyelid too. The hard-scaled animals also do this same thing—for example, the lizards and the other animals of the same kind as these; for they all close their eyes with the lower eyelid, but they do not blink like the birds.

Further, birds have neither hard-scales nor hair, but feathers; and all the feathers have quills. They have no tail, but a rump;[73] the long-legged and web-footed ones have a short one, the contrary sorts a long one. The latter fly with their feet held close to the abdomen, while the small-rumped ones fly with their legs stretched out.

All of them have a tongue, but this is not [always] the same; for some have a long
504b1 tongue, others a short [broad] one. Most of all the animals, after the human being, certain kinds of birds emit articulate sounds: the broad-tongued birds are especially of this sort.[74]

No egg-laying animal has an epiglottis over the windpipe, but they contract and open the duct so that nothing heavy goes down into the lung.

Some kinds of birds also have spurs; but none is both crook-taloned and spurred. The crook-taloned ones are included among the flyers; the spurred ones, among the ones with a burdensome flight.

Further, some birds have a crest; in some it consists of erect feathers, but in the chicken alone it is special: for it is neither flesh nor far from flesh in nature.

2.13
The Fishes

Among the aquatic animals, the fish kind constitutes one group marked off from the others, encompassing many forms.

70. *PA* 695a23–26.
71. Reading κολιῶν.
72. *GA* 749b10–25.
73. *PA* 697b11–13.
74. 597b25–29.

They have a head, back, and underneath parts, in which place are the abdomen and the viscera. Behind they have a tail that is continuous [with their bodies], and not separate, but not the same in all of them. No fish has a neck, or any limb, or any testicles at all, either internal or external, or any breasts. In general, the non-live-bearing animals are no different in this latter respect, nor are all the live-bearing ones, but only the ones that are internally live-bearing from the outset and not first egg-laying. For in fact the dolphin is live-bearing, which is why it has two breasts, not high up, but near the sexual parts. It does not have visible nipples like the four-footed animals, but, as it were, two flow-holes, one on each flank, from which the milk flows, and the offspring get suckled by following alongside, as has been clearly seen by some people.

The fishes, then, as was said, have neither breasts nor any visible external duct belonging to sex organs. But special to them is the possession of gills, with which they emit water taken in through the mouth, and fins, of which most have four, though the elongated ones (for example, the eel) have two, situated near the gills. It is the same way with the mullets (for example, those in the lake at Siphae) have two, and the so-called tape fish[75] are the same way. But some of the elongated fishes have no fins at all (for example, the muraena), nor are their gills articulated like those of the other fishes.

Among the ones having gills, some have covers for the gills, though all of the selachians have no covers. All of those having covers have the gills at the sides, though among the selachians, the broad ones have the gills down below on the underneath parts (for example, the torpedo fish and the ray), while the elongated ones have them on the sides (for example, all the shark-like fishes). The fishing frog has them on the side, but not with spinous covers like the non-selachian-like ones, but with a skin-like one.

Further, among the ones having gills, those of some are simple, those of others double; but the last one by the body is simple in all of them. Again, some have few gills, others have numerous ones; but all have an equal number on both sides. Those that have the least number have one gill on each side, but a double one—for example, the cuckoo fish.[76] Others have two on either side, one simple and one double—for example, the conger and the parrot wrasse. Others have four simple ones on either side—for example, the *elops*, the *sunagris*, the muraena, and the eel. Others have four, but in two rows, except for the last—for example, the rainbow wrasse, the perch, the sheatfish, and the carp. All the shark-like fishes have double ones, five on each side; the swordfish eight double ones. As regards the number of gills in the fishes, then, it is this way.

Further, in relation to the other animals, the fishes are distinguished by a difference other than the possession of gills; for they neither have hair like the live-bearing terrestrial animals, nor hard-scales like some of the egg-laying four-footed ones, nor

75. Identity unclear.
76. $535^{b}18$.

feathers like the bird kind. Instead, most of them are soft-scaled, though a few are rough-skinned, and a very few smooth-skinned. Among the selachians, some are rough-skinned, others smooth-skinned: the conger, the eel, and the tuna are among the smooth-skinned ones.

All the fishes are sawtoothed except the parrot wrasse; and all have many rows of sharp teeth, in some cases on the tongue. They have a tongue that is hard and prickly, and attached in such a way that they sometimes seem not to have one. As for the mouth, some have one that opens wide, like certain live-bearing[77] four-footed animals, [others a tapering one].[78]

Among the organs of perception other [than the eyes], they have none that is apparent, either itself or the ducts, either of hearing or of smelling; but they all have eyes, without eyelashes, and their eyes are not hard.

505b1 The entire fish kind is blooded. Some of them are egg-laying, some live-bearing: all the soft-scaled ones are egg-laying; all the selachians are live-bearing, except the fishing frog.

2.14
The Snakes

Among the blooded animals, the snake kind remains. It is common to both [elements]: most of them are terrestrial, but a few, the aquatic ones, spend their lives in fresh water. There are also sea snakes,[79] much the same in shape as the terrestrial ones, in all respects except that the head they have is more like the conger's. There are many kinds of sea snakes, and they have a color that varies greatly. These do not live in very deep waters. The snakes are footless like the fish kind.

There are also sea millipedes,[80] much the same in appearance as the terrestrial ones, but slightly smaller in size. These live in rocky places. They have a redder color, more feet, and thinner legs than the terrestrial ones. And they, like the snakes, do not live in very deep waters.

Among small rock fishes there is one they call the "ship-detainer":[81] some use it [to bring luck] in lawsuits and as a love charm. It is inedible. Some people say that it has feet: it does not, but appears to do so because its fins are like feet.

———

As for the external parts of the blooded animals, then, it has now been stated how many they are, of what sorts, and what differences they exhibit in relation to each other.

77. Perhaps "egg-laying" should be read.

79. 621a2–6.
80. 621a7–12.
81. Thought to attach itself to ships, impeding their progress.

2.15
The Internal Parts of the Blooded Animals

As for how the internal parts are, this must be stated in the case of the blooded animals first; for it is in this that the chief kinds differ from the rest of the other animals, by some being blooded and others bloodless. Blooded are the human being and the live-bearing four-footed animals; further, the egg-laying four-footed animals, the bird, the fish, the cetacean, and any other that is nameless because there is no kind, but rather a simple form applying to the particular cases—for example, the snake and the crocodile.

All the live-bearing four-footed animals, then, have a gullet and a windpipe that are situated in the same way as in human beings. It is likewise too in the egg-laying four-footed animals and in the birds. But they differ in the forms of these parts. Generally speaking, all those that take in air by inhaling and exhaling have a lung, a windpipe, and a gullet, and the position of the gullet and of the windpipe is always the same, though the parts are not the same, and the lung is neither the same nor does it have the same position.

Further, all the blooded animals have a heart and a diaphragm (the so-called mid-riffs). But in small animals, because of the smallness and fineness of the parts, this is not equally apparent, except in the case of the heart. There is something special in the case of the cows; for there is a kind of cow that has, though not in all cases, a bone in the heart. The heart of the horses also has a bone.

Not all of them have a lung—for example, the fishes do not, nor do any of the other animals that have gills. But all the blooded animals also have a liver, and most of the blooded ones also have a spleen. Most of the animals that are not live-bearing but egg-laying have a spleen so small that it almost escapes perception, as in most of the birds—for example, the pigeon, the kite, the hawk, and the owl. The *aigokephalos*[82] has no spleen at all. In the case of the egg-laying four-footed animals it is the same way; for these too have an altogether small spleen—for example, the turtle, the freshwater turtle, the toad, the lizard, the crocodile, and the frog.

Among the animals, some have a gallbladder near the liver, and some do not. Among the live-bearing four-legged ones, the deer does not have one nor does the roe deer—or, further, the horse, the mule, the ass, the seal, and some of the pigs. Among the deer, the so-called *achainês*[83] seem to have a gallbladder in their tail; but while what is so-called is certainly like a gallbladder in color, it is not on the whole so liquid, although its inside parts are like those of the spleen.

All deer have larvae[84] living in their heads; they are born in the hollow region under the root of the tongue and near the vertebrae to which the head is attached; in

82. Perhaps a sort of owl.
83. Perhaps a name for a second-year stag. Also at $611^{b}18$.
84. Those of a gadfly, *Oestrus rufibarbis*.

size they are no smaller than the largest maggots. They are born clinging together in masses, and their number is most often around twenty.

Deer, then, do not have a gallbladder, as was said,[85] but their intestine is so bitter that not even dogs are willing to eat it, unless the deer is very fat. The elephant too has a liver without a gallbladder, but when the animal is cut open in the place where the gallbladder naturally grows in those that have it, a gall-like liquid flows out in larger or smaller quantities.

Among the animals that take in seawater and have a lung, the dolphin does not have a gallbladder. The birds and the fishes all have one, as do the egg-laying four-footed animals, generally speaking, to either a greater or lesser extent. Some fishes, however, have it near the liver—for example, the shark-like fishes, the sheatfish, the angelfish, the ray, the torpedo fish, and (among the long fishes) the eel, the pipefish, and the hammerhead shark. The *kalliônumos*[86] also has it near the liver, and, among the fishes, it has the largest one for its size. Others have it beside the intestines, attached to the liver by certain very thin ducts. The bonito has the gallbladder extended along the intestine and of equal length, and often has a double fold. Others have it near the intestines, some further off, others closer to it—for example, the fishing frog, the *elops*, the *sunagris*, the muraena, and the swordfish.

Often too the same kind appears to have the gallbladder in either place—for example, some congers have it near the liver, others have it below and detached from the liver. It is likewise in the case of the birds; for some have the gallbladder near the stomach, others near the intestines—for example, the pigeon, the raven, the quail, the swallow, and the sparrow. But some have it at the same time near the liver and near the stomach—for example, the *aigokephalos*; others have it at the same time near the liver and near the intestines—for example, the hawk and the kite.

2.16
The Kidneys and the Bladder

All the live-bearing four-footed animals have kidneys and a bladder. Among the egg-laying [non-four-footed ones], none has them (for example, neither the bird nor the fish does), and among those that are four-footed, the sea turtle alone has these parts proportional in size to the other parts. The sea turtle has kidneys like those of the cows; that of the cow is, as it were, one kidney composed of many small ones. The bison too has all its internal parts like those of the cow.

85. 506[a]22.
86. Perhaps *Uranoscopus scaber*.

2.17
The Position of the Heart

The position of these parts in all the animals that have them is similar: the heart is in the middle, except in the human being; in it, it is more on the left, as was said **507^{a}1** previously.[87] Among all animals, the heart has its point turned toward the front; except in the case of the fishes, in which it may not appear to be so; for they do not have the point directed toward the chest, but toward the head and the mouth. And the point of their heart is attached [to a duct] where the right and left gills meet each 5 other. There are also other ducts extending from the heart to each of the gills, larger in the larger fishes, smaller in the smaller ones. But the one at the point of the heart of the large ones is a very thick white pipe.

A few fishes have a gullet (for example, the conger and the eel), but a small one. 10

Among the animals that have a liver, in those that have an undivided one it is situated wholly on the right side; in those in which it is divided from its starting-point, the larger part is on the right side. For in some fishes the parts are detached from each other and are not attached at the starting-point—for example, among the fishes, the shark-like fishes. And there is also a kind of hare around Lake Bolbe, in so-called 15 Figland, as well as in other places, that might seem to have two livers because of the distance between the connecting ducts, as is the case with the lung of birds.

In all animals, the spleen, when in accord with nature, is on the left side, and the kidneys, in those animals that have them, are situated in the same way. Cases have 20 been observed in some of the four-footed animals, when they were opened up, of having the spleen on the right side and the liver on the right; but these are judged to be monstrosities.

In all animals the windpipe extends to the lung (in a way we will describe later[88]), and the gullet extends to the stomach through the diaphragm, in those that have 25 a gullet; for most of the fishes, as was said previously,[89] do not have one, and the stomach is directly connected to the mouth. That is why in some large fishes, when they are pursuing smaller ones, the stomach[90] falls forward into the mouth.

All the animals mentioned have a stomach, and one similarly situated (for it is 30 situated directly under the diaphragm), with an intestine connecting to it and ending at the outlet for the nourishment that is called the "rectum." But they have stomachs that are dissimilar. For, first, among the live-bearing four-footed animals, the ones that are horned but do not have two rows of teeth have four places[91] of this sort: 35 these, of course, are the ones said to chew the cud.[92] For their gullet, starting from

87. 496^{a}16.
88. E.g., *PA* 665^{a}19–21.
89. 507^{a}10.
90. Actually the air bladder; also 591^{b}6.
91. Reading τόπους as at 507^{a}36.
92. The ruminants.

the mouth, extends downward near the lung, from the diaphragm as far as the large
507ᵇ1 stomach. It is rough on the inside and divided. Attached to it near the entrance of the gullet is what, from its appearance, is called the "net"; for outside it is like the
5 stomach, but inside it is like a net. The net is much smaller in size than the [large] stomach. Connected to it is the vase, rough on the inside and laminated, which is much the same as the net in size. After that is what is called the "reed," larger than
10 the vase in size and more elongated in shape; on the inside it has many smooth folds. Directly after this is the intestine.

The horned animals that do not have two rows of teeth have a stomach of this sort, though they differ from each other in the shapes and sizes of the parts, and also in that the gullet in some extends to the stomach in the middle, in others on the
15 side. The animals that have two rows of teeth have one stomach—for example, the human being, the pig, the dog, the bear, the lion, and the wolf. The *thôs*[93] too has all its internal parts like in the wolf.

All these, then, have one stomach, and coming after it an intestine. But some have a comparatively large stomach, like the pig and the bear (and that of the pig has a
20 small number of smooth folds); some have a much smaller one, not much larger than the intestine, like the lion, the dog, and the human being. And, as for the others, the forms vary along the lines of the stomachs of those mentioned; for some have one like that of the pigs, others like that of the dogs, and likewise the bigger and the smaller
25 animals. The difference in these is with respect to the sizes, shapes, and thickness or thinness of the stomach, and also with respect to the position of the point of connection of the gullet.

The nature of the intestines also differs in each of the two groups of animals that were mentioned (those that do not have two rows of teeth and those that do have two
30 rows of teeth) in size, in thickness, and in folding.

The intestines of animals that do not have two rows of teeth are all larger; for all these animals themselves are larger; for few of them are small, and no horned animal is altogether small. Some animals have appendages to the intestines, but no animal that does not have two rows of teeth has a straight intestine.

The elephant has an intestine with appendages, so that it appears to have four
35 stomachs. In this too the nourishment appears, and it has no receptacle for it apart from this. The viscera it has are much the same as those of the pigs, except that the
508ª1 liver is four times as large as that of the cow, and so are the other viscera, though the spleen, in proportion [to the size of the animal], is smaller.

The nature of the stomach and the intestines in the egg-laying four-footed animals
5 is the same way—for example, the land turtle and the sea turtle, the lizard, both sorts of crocodiles,[94] and, in general, all animals of this sort; for they have one simple stomach, in some cases like that of the pig, in others like that of the dog.

93. Perhaps the stoat or civet (also 580ª25, *GA* 742ª9, 744ᵇ16).
94. I.e., water and land (actually a large lizard).

The snake kind is similar and in pretty much all respects has parts that are much the same as, among the egg-laying footed animals, the lizards—if one imagined these to be elongated and deprived of feet. For it is hard-scaled and has back and underneath parts that are much the same as those of the lizard—except that it does not have testicles, but instead, like the fishes, has two ducts that converge into one, and a womb that is long and divided in two. The rest of its internal parts are the same as those of the lizards, except that, because of its narrowness and length, all the viscera are narrow and long, so that they are apt to escape notice due to the similarity of the shapes. They have a very long windpipe and their gullet is longer still. The starting-point of the windpipe is so close to the mouth itself that the tongue seems to be underneath the windpipe; and the windpipe seems to project over the tongue because the tongue is contracted and does not stay in place as in the other animals. The tongue is thin, long, and black, and comes out a long way. A special affection of the tongue of the snakes and the lizards in comparison to those of the other animals is that the tip is divided in two, especially the tongue of the snakes; for the tips of theirs are as thin as hairs. The seal also has a divided tongue.

The snake has a stomach that is like a spacious intestine, similar to that of the dog. Next is the intestine, which is long, thin, and a single one to the end. The heart is next to the larynx, and is small and kidney-like; that is why it may sometimes seem not to have its point directed toward the chest. Next is the lung, which is simple, articulated by a fibrous duct, very long, and well separated from the heart. The liver is long and simple, the spleen is small and round, as in the lizards. It has a gallbladder like that of the fishes; for the water snakes have it near the liver, while the others for the most part have it near the intestines. All are sawtoothed. They have ribs equal in number to the days of the month; for they have thirty.

Some people say that precisely the same thing occurs with the snakes as also occurs with swallow chicks; for if one pricks out the eyes of snakes, they say that they grow again. Also, the cut-off tails of lizards and snakes grow back.

The intestines and the stomach of the fishes are the same way; for they have one simple stomach, though differing in shapes. For some of them have an altogether intestine-like stomach—for example, the one they call the "parrot wrasse," which also seems to be the only fish to chew the cud. And the whole length of the intestine is simple, and if it has a convolution, it gets unloosed into one.[95]

A special affection of the fishes and of most of the birds is to have appendages [to the intestines], but the birds have them low down and few in number, while the fishes have them high up near the stomach, and some have many of them—for example, the goby, the burbot,[96] the perch, the *skorpios*,[97] the *kitharos*,[98] the red mullet, and the sea bream. The mullet has many on one side of the stomach and

95. $509^{a}16–17$.
96. Reading γαλῆ.
97. A species of *Scorpaena*.
98. Perhaps the sole or the turbot.

one on the other side. Some have only a few of them—for example, the *hêpatos* and the *glaukos*. The gilthead also has only a few. These fishes also differ from each other—for example, one gilthead will have more, another fewer. There are some fishes that have none at all—for example, most of the selachians. Among the others, some have few, others a great many. But all the fishes have the appendages near the stomach.

The birds exhibit a difference in their internal parts both in relation to each other and in relation to the other animals. For some have a crop in front of the stomach—for example, the chicken, the wood pigeon, the pigeon, and the partridge. The crop is a large hollow skin into which the nourishment in its first state enters and is unconcocted. At the point where it leaves the gullet it is very narrow, then it is broader, and where it reaches the stomach it is thinner again. Most birds have a stomach that is fleshy and firm, and inside it is a strong skin that can be pulled away from the fleshy part. Other birds do not have a crop, but in place of it a gullet that is broad and large, either throughout the whole of it, or where it extends to the stomach—for example, the jackdaw, the raven, and the crow. The quail also has a gullet that is large below, and the *aigokephalos* has one that is a little wider below, as does the little owl. The duck, the goose, the gull, the *katarraktês*, and the great bustard have a gullet that is broad and large throughout, and many of the other birds likewise. Some have a part of the stomach that is like a crop—for example, the kestrel. There are some that have neither a crop nor a wide gullet but a long stomach; these are the small birds—for example, the swallow and the sparrow. A few have neither a crop nor a wide gullet, but rather a very long one; these are the ones that have a long neck—for example, the *porphuriôn*; and pretty much all these birds emit a wetter residue than the other birds. The quail has these parts in a special way in comparison to the other birds; for it has a crop and, in front of the stomach, a gullet that is wide and large. The crop is a long way distant, in proportion to the bird's size, from the gullet where this is in front of the stomach.

Most have an intestine that is thin and simple when uncoiled. The birds have appendages, as was said,[99] that are few in number, and these are not high up, as in the fishes, but low down near the end of the intestine. Not all have them, but most do—for example, the chicken, the partridge, the duck, the night raven, the *lokalos*, the *askalaphos*,[100] the goose, the swan, the great bustard, and the owl. Some of the small birds also have them, but altogether small ones—for example, the sparrow.

99. 508^b15.

100. Perhaps an owl of some sort.

BOOK 3

3.1
The Parts Involved in Generation

The other internal parts—how many they are, their qualities, and the differences they exhibit in relation to each other—have now been spoken about. It remains to speak about the parts that contribute to generation. For though in all females these are internal, those of the males exhibit many differences.

Among the blooded animals, some have no testicles at all; some have them, but have them internally (and among those having them internally, some have them near the loin, beside the place of the kidneys, others have them near the abdomen); and some have them externally. And the sex organ of these is in some animals closely attached to the abdomen, in others it is loose, as too are the testicles. It is closely attached to the abdomen in one way in the animals that urinate forward and those that urinate backward.

Among the fishes, none has testicles, nor does any other animal that has gills, nor any of the whole snake kind, nor, in general, any footless animal that is not internally live-bearing. Birds have them, but have them internally close to the loin. And among the egg-laying four-footed animals it is the same way—for example, the lizard, the turtle, and the crocodile, and, among the live-bearing ones, the hedgehog. Among those that have them internally, some have them close to the abdomen—for example, among the footless ones, the dolphin, and, among the live-bearing four-footed animals, the elephant. Others have them plainly visible.

The attachment of the testicles to the stomach and the place continuous with it and what sort of difference it exhibits was spoken about previously;[101] for in some they are continuous from the rear and are not detached—for example, in the pig kind, while in others they are detached—for example, in the human beings.

The fishes do not have testicles, as was said previously,[102] nor do the snakes. They have two ducts connected to the diaphragm on either side of the spinal column, converging into a single duct above the outlet for the residue. By "above" we mean toward the spinal column. In the mating season, these ducts become full of seminal fluid, and when they are squeezed, the seed, which is white, emerges. But one must observe with the help of the *Dissections* the differences these parts exhibit in relation to each other; these will be stated more exactly later on in the discussions concerning what things are special to each of these.

The [males of the] egg-laying animals, whether two-footed or four-footed, all have testicles that are near the loin underneath the diaphragm, some more white, others more yellow, and they are altogether encompassed by very thin small blood vessels.

101. $500^{a}33–^{b}15$.
102. $508^{a}12–14$.

From each a duct extends, and the two converge into one, just as in the fishes, above the outlet for the residue. This is the sex organ. In the small ones it is not clear to perception, but in the larger ones (for example, the goose and animals of such size) it becomes more evident when mating has recently occurred.

The ducts both in the fishes and in these animals[103] are attached to the loin under the stomach and the intestines, between these and the great blood vessel, from which ducts extend to both of the testicles. As in the fishes, in mating season the seminal fluid appears in the ducts and the ducts become very clear to perception, but when the season is over, the ducts are sometimes invisible, as is also the case with the testicles of the birds. Before mating, birds have testicles that are in some cases small, in others altogether invisible; but when they are mating, they have very large testicles. This occurs in a way that is most noticeable in the wood pigeons and the partridges, so that some people think that in winter these birds have no testicles at all.

Among the animals that have the testicles in the front, some have them internally near the abdomen, like the dolphin. Others have them externally, in plain view, near the end of the abdomen. In the case of these animals, though in other respects they are the same way, they differ in that some have the testicles by themselves, while others (the ones that have them externally) have them in what is called the "scrotum."

In all the live-bearing footed animals, the testicles themselves are the following way. From the aorta blood vessel–like ducts extend to the head of each testicle, and two others from the kidneys. The latter are bloodlike, those from the aorta bloodless. From the head of the testicles, along the testicle itself, there is a duct denser and more sinewy than the others that bends back again in each of the testicles toward its head; and again from the head of each the ducts extend until they join together in the front, at the sex organ. The ducts that bend back and those that lie along the testicles are surrounded by the same membrane, so that it seems to be one duct, unless one cuts open the membrane. In the duct that lies along the testicles the liquid is still bloodlike, though less so than the higher-up ones coming from the aorta; in the ducts that bend back toward the tube in the sex organ the liquid is white. A duct also leads away from the bladder and joins together with the upper part of the tube; and around this is a sort of sheath called the "sex organ."

One may observe the things that were mentioned in the following diagram [Fig. 1]:

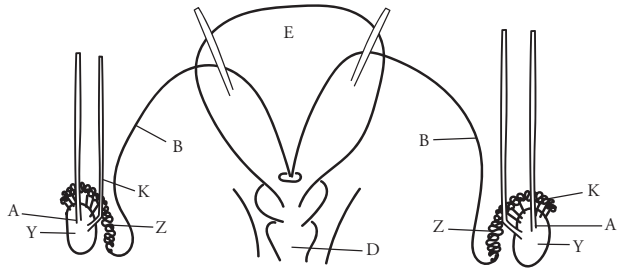

Fig. 1

103. The egg-laying four-footed ones.

A is the starting-point of the ducts from the aorta. KK are the heads of testicles and the ducts that come down into them. ZZ are the ducts extending from the previous ones to the testicles. BB are the ducts that turn back, in which the white liquid is present. D is the sex organ, E the bladder, and YY the testicles.

When the testicles themselves are severed and removed, the ducts are drawn up. People destroy the testicles of animals by rubbing when they are still young, or by **510^{b}1** cutting them out later on. But a case has been known of a bull being castrated and immediately afterward mating and begetting an offspring.

These, then, are the ways the testicles are in the animals.

The uterus in the animals that have a uterus is neither the same way nor is it the same in all; instead, it differs both among the live-bearing animals in relation to each other and among the egg-laying ones. It is divided in two in all those that have the uterus near the sexual parts, and one of its branches is toward the right, the other toward the left. But its starting-point is a single one and its mouth a single one; it is like a very fleshy and cartilaginous tube in most of the largest animals. One of these parts is called the *hustera* and *delphus* (from which the word *adelphos*[104] derives), the other part, the tube or mouth of the uterus is called the *mêtra*. In all the live-bearing two-footed and four-footed animals, the uterus is below the diaphragm—for example, the human being, the dog, the pig, the horse, and the cow. It is the same way in all the horned animals. At the extremities of its so-called horns, the uterus of most animals has a coil.

In the case of those animals that are externally egg-laying, the uterus is not similarly situated in all; instead, that of the birds is near the diaphragm, that of the fishes down below, just as in the live-bearing two-footed and four-footed animals, except that it is thin, membranous, and long, so that in very small fishes, each of the two parts of the uterus seems to be one egg. On the supposition that these sorts of fishes have only two eggs, they are the ones whose eggs are said to be crumbly; but, in fact, each of the parts has not one egg but many; that is why it breaks into many pieces.

The uterus of the birds has a tube below that is fleshy and firm, and a part near the diaphragm that is membranous and so altogether thin that the eggs might seem to be outside the uterus. In the larger birds the membrane is more clearly visible, and if inflated through the tube it rises and swells out. In the small birds all these parts are less visible.

The uterus is also the same way in the egg-laying four-footed animals—for example, the turtle, the lizard, the frog, and the others of this sort; for the tube below is a single one and fleshy, and the divided part and the eggs are up at the top near the **511^{a}1** diaphragm. In those footless animals that are externally live-bearing though internally egg-laying—for example, the sharks and the other so-called selachians (for an animal that is footless, has gills, and is live-bearing is called a "selachian")—the uterus is divided in two, and likewise extends to the diaphragm, as in the birds. Further,

104. "Brother."

through the middle of the two branches, starting from down below, it extends until it reaches the diaphragm, and the eggs are produced here and above at the starting-point of the diaphragm. Then they advance into the wider space, and animals come to be from the eggs. But the differences in the uterus of these fishes in relation to each other and also in relation to the other fishes may be more exactly observed with the help of the diagrams in the *Dissections*.

The snake kind also exhibits difference both in relation to these animals and in its members, relations to each other. For, though all the other kinds of snakes are egg-laying, the viper alone is live-bearing, though it is internally egg-laying first; that is why its uterus is much the same as that of the selachians. The uterus of the snakes is long, as is their body, and starting below from a single duct it extends continuously on either side of the spinal column—as if there were a single duct on each side—until it reaches the diaphragm; there the eggs appear in a column; and they are laid not one by one but in a continuous strand.[105]

All the animals that are live-bearing both internally and externally have the uterus above the stomach; those that are egg-laying all have it below, near the loin. All the ones that are externally live-bearing but internally egg-laying play a double game; for the lower part of the uterus, in which the eggs are, is near the loin, while the part around the outlet is above the intestines.

There is a further difference exhibited by one uterus in relation to another. For the horned animals that do not have two rows of teeth have cotyledons in the uterus when it contains the fetus, and so have the ones that do have two rows of teeth—for example, the hare, the mouse, and the bat. The other live-bearing footed animals with two rows of teeth all have a smooth uterus, and the attachment of the fetus is to the uterus itself and not to a cotyledon.

The non-uniform parts are in the animals in these ways, then, both the external ones and the internal ones.

3.2
The Blood Vessels (1)

511[b]1 Among the uniform parts, the most common one in all the blooded animals is the blood and the part in which it naturally appears (this is called a "blood vessel"); next come the analogs of these, serum and fibers, and that which most constitutes the body of animals, flesh and the analog of this in each part; further, bone and the analog of this—for example, spine and cartilage; further, skin, membrane, sinew, hair, nails, and the ones that correspond to these; and in addition, fat, suet, and the residues (excrement, phlegm, and yellow and black bile).

105. 558[b]1–2.

But since the nature of blood and that of the blood vessels seems to be a starting-point, these must be spoken about first—all the more as some of those who spoke about them previously did not speak about them correctly. The cause of ignorance is the difficulty of their being observed. For in dead animals the nature of the blood vessels with the most control is invisible, principally because they collapse immediately when the blood leaves them (for the blood pours out all at once like liquid from a vessel; for there is no blood that is by itself, except for a little in the heart—all of it is in the blood vessels). In the living animals it is impossible to observe how these parts are; for their nature is internal. As a result, those who have made their observations on dead and cut-open animals have not observed the most important starting-points, while those who have made them on very thin human beings[106] have based their determinations about the starting-points of the blood vessels on what was then apparent externally.

Syennesis, the doctor from Cyprus, speaks in this way: "The nature of the thick blood vessels is this: from the navel along the loin, across the back, along the lung, under the breasts; one from right to left, the other from left to right; the one from the left through the liver to the kidney and the testicles; the one from the right, to the spleen, kidney, and testicles, and from there to the sex organ."

Diogenes of Apollonia says this: "The blood vessels in the human being are as follows: There are two large ones; these extend through the stomach along the spinal column, one to the right, the other to the left, each to the leg on its own side [of the body], and upward to the head, along the clavicles through the throat. From these, blood vessels extend to the whole body, from the one on the right to the right side, **512^{a}1** from the one on the left to the left side; the two largest ones go to the heart near the spinal column, while others, a little higher up, go through the chest under the armpits, each to the hand on its own side; one of the these is called the 'splenetic,' the other the 'hepatic.' Each of them divides in two at its extremity, one part going to the thumb, the other to the palm of the hand; from these a number of thin blood vessels with many branches go to fingers and the rest of the hand. Other yet thinner ones extend from the primary blood vessels, from that on the right to the liver and from that on the left to the spleen and the kidneys. The ones that extend to the legs divide in two at the point of attachment [of the legs and the trunk], and extend through the entire thigh. The largest of them[107] goes down the back of the thigh, and shows its thickness; the other is on the inside of the thigh, and is slightly less thick than the first. Then they extend along the knee to the shank and the foot. And like those that go to the hands, they reach to the sole of the foot, and from there they extend to the toes. From these large ones many thin blood vessels divide off toward the stomach and the rib.

106. In whom the blood vessels (the veins and arteries) were easier to see.
107. The femoral artery.

"The blood vessels that extend to the head through the throat[108] are evident as large ones in the neck. From each of these two, at the point where it ends, many blood vessels divide off to the head, some from the right toward the left, some from the left toward the right; each of the two ends beside the ear. There is another blood vessel in the neck on either side of the large one, a little smaller than it, to which most of the blood vessels from the head are connected. These extend through the throat on the inside, and from each of these blood vessels extend below the shoulder blades to the hands; and other blood vessels, slightly smaller in size, are evident along the splenetic and hepatic vessels; these are the ones that are opened when any pain is felt under the skin, while if any is felt in the region of the stomach, it is the hepatic and the splenetic ones. From these, other blood vessels extend below the breasts.

512b1 "Others—thin ones—extend on each side through the spinal marrow to the testicles. Others extend under the skin and through the flesh to the kidneys; these terminate at the testicles in men and, in women, at the uterus. The blood vessels coming from the stomach are at first broader, then become thinner, until they change from right to left and from left to right. They are called the 'spermatic' ones.

"The coarsest-grained blood is absorbed[109] by the fleshy parts; but when it runs over into the places mentioned, it becomes thin, hot, and foamy."

3.3
The Blood Vessels (2)

Syennesis, then, and Diogenes spoke in this way, Polybus in the following one: "There are four pairs of blood vessels. One comes from the back of the head through the neck on the outside along both sides of the spinal column until it reaches the haunches and the legs, then it goes through the shanks to the outer parts of the ankles[110] and the feet. And that is why, for pains in the back and the loin, blood-letting incisions are made in the hams and the outer parts of the ankles.

"Other blood vessels go from the head, along the ears, through the neck. These are the so-called jugulars; each of them goes along the spinal column on the inside, along the loin muscles, to the testicles and the thighs, through the inner parts of the hams, through the shanks to the inside of the ankles and the feet. And that is why, for pains in the loin muscles and the testicles, blood-letting incisions are made in the hams and the inside of the ankles.

"The third pair, going from the temples through the neck under the shoulder blades, reaches the lung. The ones from the right to the left go under the breast to the

108. The jugular veins.
109. Reading ἐκπίνεται.
110. Reading εἰς τῶν σφυρῶν τὸ ἔξω.

spleen and kidney; those from left to right go from the lung under the breast to the[111] liver and the kidney: both end in the anus.

"The fourth pair goes from the front of the head and the eyes underneath the neck and clavicles; from there they extend through the upper part of the arms to the elbows, then through the forearms to the wrists and the joints of the fingers, through the lower part of the upper arms to the armpits, above the ribs, until one of them reaches the spleen and the other the liver; then, passing over the stomach, they both end up in the sex organ."

This, then, is pretty much what others have said. There are also some writers about nature who have not busied themselves with giving such an exact account of the blood vessels, but who all alike put the starting-point of these in the head, that is, in the brain—which is not correct. But since observation is difficult, as was said previously, if one cares about these sorts of things, it is only in animals emaciated beforehand and then strangled that it is possible to learn adequately about them.

This is the way the nature of the blood vessels is. There are two blood vessels in the thorax, along the spinal column on the inside; of these, the larger one is situated in front, the smaller one behind it; the larger is more toward the right side of the body, the smaller toward the left, and called the "aorta" by some people, from the fact that even in dead bodies its sinewy part is observed.[112] These blood vessels have their starting-point in the heart; for they go through the other viscera, in whichever direction they happen to extend, wholly preserving themselves as blood vessels in passing through these, while the heart is, as it were, a part of them, and more so of the front larger one, because these are above and below, while the heart is in the middle of them.

All hearts have cavities in them, but in those of the very small animals the largest is scarcely visible; in the middle-sized ones, the second also is; but in the largest ones the three are visible. The heart has its pointy end turned toward the front, as was said previously;[113] the largest cavity is on the right side, and highest up; the smallest one is on the left; and the middle-sized one is in the middle of these two. Both of the latter are much smaller than the largest one. All three, however, are connected by ducts to the lung, but these are invisible because of the smallness of the ducts, except for one.[114]

The great blood vessel is attached to the largest cavity, the one that is uppermost and on the right side; then it goes through the middle cavity and extends out as a blood vessel again, as if the cavity were a part of the blood vessel in which the blood forms a lake. The aorta is attached to the middle cavity; except not in this way, but is connected to it by a much narrower passage. And though the great blood vessel goes through the heart, [the passage] that leads to the aorta extends from the heart. The great blood vessel is membranous and skin-like, while the aorta is narrower than

111. Reading εἰς τὸ.
112. An *aortêr* is also a "means of support," as the sinewy aorta might be taken to be.
113. 496^{a}10.
114. Perhaps the pulmonary artery.

it, and very sinewy; as it extends further toward the head and the lower parts of the body, it becomes altogether narrow and sinewy.

First, then, there is a part of the great blood vessel that extends from the heart toward the lung and the attachment of the aorta; this part is a large and undivided blood vessel. It is divided into two parts, one going toward the lung and one toward the spinal column and the last vertebra of the neck. The blood vessel that extends toward the lung, which is itself double, divides into two at first, then extends along each passage and each aperture, being larger along the larger ones, smaller along the smaller ones, in such a way that one cannot find any part at all where there is not both an aperture and a small blood vessel; for the end-points are invisible because of their extreme smallness, while in fact the entire lung appears full of blood. The ducts from the blood vessel are situated above the pipes that extend from the windpipe. And the blood vessel extending to the vertebra of the neck and the spinal column extends back again along the spinal column, as Homer says in his poem: "All that blood vessel he cut through that runs all the way up the back till it reaches the neck."[115] And from this blood vessel, small blood vessels extend along each rib to each vertebra, and at the vertebra above the kidneys the blood vessel divides into two.

These parts, then, divide off from the great blood vessel in these ways. But above these, from the part extending from the heart, the whole blood vessel, dividing again, goes to two places. For these go to the sides and the clavicles, then through the armpits to the arms in the human beings, to the front legs in the four-footed animals, to the wings in the birds, and to the pectoral fins in the fishes.

The starting-points of these blood vessels, where they first divide off, are the so-called jugulars, and where they divide off to the neck, they extend along the windpipe. (Sometimes, when these are pressed on the outside, people—without choking—fall down unconscious, their eyes closed.) Extending on in this way, keeping the windpipe between them, they go on to the ears, at the point where the jaws join the head. Then again from that point they divide off into four, one part[116] of which bends back and descends through the neck and the shoulder, and joins the former dividing off from the blood vessel at the bend of the arm, while the other part ends up in the hand and the fingers.

Each one of the other pair extends from the place around the ears to the brain, and divides up into many thin small blood vessels into what is called the "meninx," which surrounds the brain. The brain itself is bloodless in all animals and no blood vessel, whether small or large, ends in it. Among the rest of the blood vessels that divide off from this blood vessel, some encircle the head, others end in the perceptual organs and the teeth by means of altogether thin small blood vessels.

115. *Iliad* 13.546–547.

116. Consisting of a pair of blood vessels (probably the facial veins and the external jugular vein).

3.4
The Blood Vessels (3)

In the same way the parts of the lesser blood vessel, the so-called aorta, divide off, following along together with those of the great blood vessel, except that the ducts are smaller and the small blood vessels of it much fewer than those of the great blood vessel.

These, then, are the ways the blood vessels above the heart are.

The part of the great blood vessel that lies under the heart extends, unsupported, through the diaphragm, and is secured to the aorta and the spinal column by loose membranous ducts. From it one blood vessel, short but broad, extends through the liver, and from it many thin blood vessels extend into the liver and disappear. From the blood vessel that goes through the liver two branches divide off, of which one ends at the diaphragm (the so-called midriffs), while the other, returning back again through the armpit into the right arm, joins the other blood vessels at the inside **$514^{b}1$** of the bend; that is why when doctors open this blood vessel people get relief from certain hepatic pains. From its left side a small but thick blood vessel extends to the spleen, and the small blood vessels that come from it enter the spleen and disappear. Another part divides off from the left side of the great blood vessel and ascends in the same way to the left arm; except that the former is the one that goes through the liver, while this one is distinct from the one extending through the spleen.

Further, other blood vessels divide off from the great blood vessel, one to the omentum, one to the so-called pancreas; and from the latter many blood vessels extend through the mesentery. All these end in a single large blood vessel, which extends all along the intestine and the stomach as far as the esophagus. And from around these parts many blood vessels divide off.

The aorta and the great blood vessel, each of the two being one single thing, extend as far as the kidneys. There they become more attached to the spinal column, and each divides into two, like the letter lambda, and the great blood vessel situates itself more at the back of the aorta. The aorta, for its part, is most attached to the spinal column near the heart; and the attachment is by means of very small sinewy blood vessels.

The aorta, where it leads away from the heart, is a hollow of considerable size, but as it proceeds it is narrower and more sinewy. From the aorta blood vessels extend to the mesentery, just like those from the great blood vessel, except that they are much inferior in size; for they are narrow and fibrous; and in fact they end in thin and intricate fibrous small blood vessels. No blood vessel extends from the aorta to the liver or the spleen.

The divided-off vessels of each of these two blood vessels[117] extend to each haunch, and both attach themselves to the bone. Blood vessels also lead to the kidneys[118] from

117. The aorta and the great blood vessel.
118. Cf. $497^{a}4$–17.

both the great blood vessel and from the aorta, except that they do not go into the cavity, but lose themselves in the body of the kidneys. From the aorta two other ducts lead into the bladder that are strong and continuous; others also lead from the cavity of the kidneys that have no connection to the great blood vessel. At the middle of each kidney a hollow and sinewy blood vessel is attached that extends along the spinal column itself through the narrow regions; then each of the two first disappears into its own haunch, then become clear to perception again extending to the haunch. The limit points of these attach to the bladder and to the sex organ in males, and in females to the uterus. No blood vessel extends from the great blood vessel to the uterus, but from the aorta many densely clustered ones do so.

Other blood vessels also extend from the aorta and the great blood vessel at the point where they divide off. Some go first to the groin and are large and hollow, then, going through the legs, they end in the feet and the toes; others, in turn, go through the groin and the thighs crosswise, from left to right and from right to left, and join together with the other blood vessels in the hams.

The way the blood vessels are, then, and from where they take their starting-points is evident from these descriptions.

In all the blooded animals, this is the way things are as regards the starting-points and the great blood vessels (for the rest of the majority of the blood vessels are not this way in all these animals; for their parts are not this way either, nor do they all have the same ones), although this fact is not equally evident in all of them, but is most so in the ones that have abundant blood and are largest. For in the small ones that do not have abundant blood, either because of nature or because of the fatness of their bodies, it is not equally possible to acquire knowledge of it; for in some of them the ducts are indistinct, as some streams are when under a lot of mud, while others have a few fibers in place of blood vessels. But the great blood vessel is most clearly distinguishable in all of them, even the smallest.

3.5
The Sinews

The sinews are the following way in the animals. Their starting-point too[119] is the heart; for the heart itself has sinews within itself, in the largest cavity; and the so-called aorta is a sinewy blood vessel. Its end-points, indeed, are altogether sinewy; for they are not hollow, and their elasticity is of precisely the same sort as that of the sinews where they end up, at the bends of the bones. Nonetheless, the nature of the sinews is not continuous from a single starting-point in the way the blood vessels are. For the blood vessels, as in the drawn mannikins,[120] have the shape of the entire body, so

119. Like that of the blood vessels.
120. *GA* 743a2, 764b29–31.

that in very thin people their entire bulk appears to be full of small blood vessels (for **515^{b}1**
the thin small blood vessels occupy the same place in thin people as flesh does in fat
ones), while the sinews are dispersed around the joints and bends of the bones. If, on
the other hand, their nature were continuous, the continuity of all of them would be 5
evident in thin people.

The most important parts of the sinews have to do with the part of the body that controls jumping (this is called the "ham"); another sinew, a double one, is the tendon;[121] also, those for promoting strength, the *epitonos* and the shoulder-sinews.[122] There are also nameless sinews around the bend of the bones; for all the bones that 10
are composed attached to each other are bound together by sinews, and around all the bones there is a large number of sinews. Except that in the head there are none: the sutures of the bones themselves keep it together.

The nature of the sinew is to be splittable lengthwise, unsplittable crosswise, and to have a lot of elasticity. Around the sinews a mucus-like liquid occurs, which is 15
white and viscous, by which the sinews are nourished and from which they apparently come about. While blood vessels can be cauterized, a sinew when cauterized is entirely destroyed; and if a sinew is cut, it does not grow back together again. Numbness never occurs where in the body there is no sinew.[123] 20

Most of the sinews are around the feet, the hands, the ribs, the shoulder blades, the neck, and the arms.

All blooded animals have sinews; but in those that have no bends, but are footless and handless, the sinews are thin and invisible; that is why in the fishes they are most clear to perception near the fins. 25

3.6
The Fibers

The fibers are intermediate between sinew and blood vessel. Some of them contain a liquid, the serum, and they extend from the sinews to the blood vessels, and from those to the sinews.

There is also another kind of fibers, which occurs in blood, but not in the blood of 30
every animal. If they are removed from the blood, it does not solidify, but if they are not removed, it does solidify. While fibers are present in the blood of most animals, no fibers are present in that of the deer, the roe deer, the antelope,[124] and some others. That is why their blood does not solidify to the same degree as that of the 35
other animals. That of the deer solidifies to much the same degree as that of the hares **516^{a}1**
(in both of these the solidification is not firm, as in the other cases, but loose, like

121. Either the Achilles tendon or the great ligament of the neck.
122. Probably the deltoid muscle.
123. Aristotle did not distinguish nerves from sinews.
124. *PA* 663^{a}11.

that of milk if one does not put into it what makes it curdle[125]). That of the antelope solidifies more; for it gets composed to much the same degree as that of the sheep, or slightly less.

As regards blood vessel, sinew, and fiber, then, this is the ways they are.

3.7
The Bones

The bones in animals are all connected to a single one and are continuous with each other, like the blood vessels; there is no bone that is by itself.

The starting-point in all animals that have bones is the spinal column. The spinal column is composed of vertebrae and extends from the head down to the loins. The vertebrae are all perforated and at the top the bone of the head, which is called the "cranium," is continuous with the last vertebra. Of this the sawtoothed part is a suture. The cranium is not the same in all animals: some, like the dog, have a cranium consisting of a single bone; others, like the human being, have one that is composite: the female one has a circular suture; the male one has three sutures that joint together at the top and are triangular-shaped. But a man's head having no sutures has been observed.

The head is composed not of four bones but of six: two of these are near the ears, and are small compared to the rest. From the head extend the jaws, which are bones. All the other animals move the lower jaw; the river crocodile, alone among the animals, moves the upper jaw.[126]

In the jaws the tooth kind is present: the tooth is a bone, part unperforated, part perforated, and is the only bone that it is impossible to engrave.

From the spinal column, which is precisely the linchpin, the clavicles and the ribs extend. The chest, for its part, is situated on ribs; but these ribs meet together, while the others do not meet together; for no animal has bones around the stomach. Further, there are the bones in the shoulders, which are called the "shoulder blades," followed by the ones in the arms, and connecting to these the ones in the hands. In those animals that have front legs, they are the same way.

Below, where the spinal column reaches its limit, after the haunch bone, there is the hip socket, and now the leg bones, the ones in the thighs and in the shanks, which **516[b]1** are called "limb bones," of which the ankle is a part, and the so-called *plêktra*,[127] in those animals that have an ankle. Continuous with these are the bones in the feet.

In all the blooded and footed animals that are live-bearing the bones do not differ much, but rather by analogy only, in hardness and softness and in size. Further, in the same animal, some bones have marrow, others do not. Some animals would seem to have

125. E.g., fig juice (*Mete*. 384[a]21) or rennet.
126. Cf. 492[b]23–24.
127. Analogous, perhaps, to the spurs of birds (also *plêktra*). See 526[a]5.

no marrow at all in their bones (for example, the lion), because of having an altogether small quantity that is fine-grained and present in few bones; but it actually has it in the thigh bones and in the arms.[128] The lion has bones that are the most solid of all; for they are so hard that when they are rubbed together sparks fly out just like from stones.

The dolphin also has bones, not spine. And among the other blooded animals, some vary but little [from these] (for example, those of the birds), while those of others are the same by analogy (for example, those in the fishes). For among these, the live-bearing ones have cartilaginous spine (for example, the so-called selachians), while the egg-laying ones have spine that is like the spinal column in the four-footed animals. A special affection in the fishes is that in some there are thin little spines separated throughout the flesh. The snake is similar to the fishes; for the spinal column it has is spinous.

Among the egg-laying four-footed animals, the larger have a more bony skeleton, while the smaller have a more spinous one. But all the blooded animals have a spinal column, whether bony or spinous. The other parts of the skeleton are present in some animals, not in others, but in having the parts [of the body] they have, they also have the bones in these parts. For all the animals that do not have legs and arms do not have limb bones either; nor do all those that do have these parts, but not the same ones; for in those the bones differ by the more and less or by analogy.

As regards the nature of the bones, then, this is the way it is in the animals.

3.8
Cartilage

The cartilage is of the same nature as the bones, but differs from them by the more and less. And just as bone does not grow back together if cut, neither does the cartilage. In the live-bearing blooded terrestrial animals the cartilages are not perforated, and there is no marrow in them as there is in the bones. In the selachians (for these have cartilaginous spine), there is present in the ones that are large, in the cartilaginous part of the spinal column, the analog of the bones, and in these there is a marrow-like liquid. In the live-bearing footed animals there are cartilages around the ears, the nostrils, and some extremities of the bones.

3.9
Nails, Hooves, Claws, Horns, and Beaks

Further, there are other kinds of parts that do not have the same nature as the preceding ones, yet are not far from them in those animals that have these parts—for example, nails, hooves, claws, and horns, and in addition to these the beak, of the sort

128. The front legs.

the birds have. For these parts are bendable and splittable, while bones are neither bendable nor splittable, but shatterable.[129]

Also, the colors of the horns, nails, claws, and hooves follow along with the color of the skin and hair. For animals with black skin have black horns, hooves, and claws (whichever ones have claws), white-skinned animals have white ones, while those of intermediate color have intermediate-colored ones. It is the same way with nails. The teeth are in accord with the nature of the bones. That is why black people, like Ethiopians and those of this sort, while they have white teeth and bones, have nails that are black, like their entire skin.

Most horns are hollow from the point of attachment to the bone that grows inside them from the bone of the head, but at the extremity they have a solid tip; and they are simple: only those of the stag are solid throughout and multi-split. No other horned animal sheds its horns. The stag alone does this: each year unless it has been castrated. (The castrated animals will be spoken about later on.[130]) Horns are more attached to the skin than to the bone; that is why in Phrygia and elsewhere there are cows that can move their horns like their ears.

Among the animals that have nails (and all those that are toed have nails, and all footed ones have toes, except the elephant; it has undivided, slightly articulated toes, but has no nails at all)—among the animals that have nails, then, some are straight-
517[b]1 nailed, like the human being, others crook-nailed [or crook-taloned], like the lion, among the walkers, and the eagle, among the flyers.

3.10
Hair (1)[131]

As regards the hair and its analogs and the skin, the following are the ways they are.

All the live-bearing footed animals have hair; all the egg-laying footed ones have hard-scales; the fishes alone—that is, the ones that lay a crumbly egg[132]—have soft-scales; for, among the long fishes, the conger does not have this sort of egg, nor does the muraena, and the eel does not have eggs at all.

The coarseness, fineness, and length of hair differ with the places where it is and with the quality of the skin. For, for the most part, the more coarse-grained the skin is, the harder and coarser is the hair, while more and longer hair is in hollower and wetter places, if indeed the place is of the sort to have hair. It is likewise for the animals that have soft-scales and the ones that have hard-scales. In the ones with soft hair, abundant feeding makes it harder; in the ones with hard hair, softer and less plentiful.

129. *Mete*. 4.8–9.
130. 631[b]19–632[a]32.
131. Also *GA* 5.3–5.
132. 510[b]25–27.

Hair also differs with the hotness and coldness of the places where it is—for example, the hair of human beings is hard in the warm ones, soft in the cold ones. Again, straight hair is soft, curly hair hard.

3.11
Hair (2) and Skin

The nature of the hair is to be splittable. But hairs differ from one another by the more and less. In some animals they change little by little in hardness until they are no longer like hairs but like spines—for example, those of the hedgehog. It is much the same way in the case of the nails; for the nail kind in some of the animals is no different from bones in hardness.

As for skin, among all the animals, the human being's is the finest-grained in relation to size. Present in all skins is a viscous mucilaginous liquid, less in some, more in others, as, for example, in those of the cow, from which people make glue. (In some places glue is also made from fishes.) The skin by itself is without perception when cut: the sort on the head especially so, because between it and the bone there is the least flesh. Wherever the skin is by itself, if it is cut, it does not grow back together—for example, the thin part of the jaw,[133] the foreskin, and the eyelid. In all animals the skin is one of the continuous parts, and has gaps [only] where, in accord with nature, the ducts for evaporation of liquid are, and at the mouth and nails. All blooded animals have skin, but not all have hair, but things are as stated previously.[134]

The hair changes color with age and becomes white in the human being. This happens in the other animals, but not noticeably, except in the horse. The hair also becomes white at the extremities. But in most cases of grayness, the hairs are white from the outset, which makes it clear that grayness is not a sort of drying-up, as some people say; for nothing grows from being at the outset dried-up.

In the eruptive disease called "white sickness," all the hair goes gray; and certain cases have been observed where those who were ill went gray, but when they became healthy the hair fell out and grew back black. Hair becomes gray more if it is kept covered than in the open air.[135] The first thing to go gray in human beings are the temples; the front parts do so before the back parts; and last the pubic region.

In the human being alone among the animals some hair is innate, while some grows later in accord with the stages of life. Innate: that on the head, the eyelids, and the eyebrows; growing later: first, the pubic hair, then that under the armpits, and

133. The cheek.
134. $490^{b}25$–30, $498^{b}16$–$499^{a}12$, $517^{b}3$–8.
135. *GA* $785^{a}25$–32.

third that on the chin. For the places in which innate hair appears and those in which later hair does are equal in number.

The hair that falls out with age is first and foremost that on the head. But only that on the front; for no one goes bald at the back. Smoothness on the top of the head is called "baldness," on the eyebrows "forehead baldness"; neither of these occurs until sexual intercourse starts.[136] No boy goes bald, nor does a woman or a castrated man; if castration takes place before puberty, the later-growing hair does not grow; if after, only it falls out, except pubic hair.

Woman does not grow hair on the chin, except that in some cases a few hairs grow when menstruation ceases, and, for example, in the priestesses in Caria, where it is believed to be a sign of coming events when it occurs. The other sorts of late-growing
518[b]1 hair occur, but in lesser quantities. There are also men and women who from birth lack later-growing hair and are at the same time infertile; these are precisely the ones who lack pubic hair.

The various sorts of hair grow in proportion[137] more or less, especially on the head, then on the chin; and fine hair most of all. In some people, as they get older, the eyebrows become so thick that they have to be trimmed; this is because they are situated where bones join together, and as people become older these bones draw apart and allow more liquid to pass through. The hairs in the eyelashes do not grow in length, but fall out when sexual intercourse starts, and more so in the lecherous ones.[138] These are the hairs that go gray most slowly.

Hairs plucked out before the prime of life grow back again, then no longer do. Every hair has at its root a viscous liquid, and immediately after being plucked out it can lift up light objects when making contact with them.

Those animals that have variegated hair also have a similar variegation preexistent in the skin and the skin of the tongue.

As regards the beard, it happens that in some men the upper lip and the chin have thick hair, while in others, though these parts are smooth, the cheeks are hairy; the smooth-chinned ones are less likely to become bald.

The hair grows in certain diseases—for example, in cases of consumption it does so more, and in old age and after death, and it becomes harder instead of soft. And the same things occur with the nails.

In the lecherous ones, the innate hair falls out more; and the later-growing hair grows more. Those who have varicose veins go bald less, and if they get them after they go bald, in some the hair becomes thicker.

A hair does not grow where it is cut, but becomes longer by growing up from below. And the scales in the fishes become harder and thicker, and they become harder in those that become thin or old. When the four-footed animals become old

136. *GA* 783[b]26–27.
137. To the quantity of liquid residue produced. See *GA* 782[b]11–18, 744[b]24–26.
138. *GA* 774[a]36–[b]2.

the hair and the fleece become longer, but their quantity diminishes. The hooves or claws get large with age, as do the beaks of birds. Claws also grow, just like the nails.

3.12
Changes of Color

As regards the feathered animals, such as the birds, none undergoes a change [of color] with age, except the crane: while it is ash-colored, its feathers darken as it grows older. Because of seasonal conditions, like when it becomes very cold, sometimes single-colored birds change from black or a darkish color to white—for example, the raven, the sparrow, and the swallow; but no white kind has been seen to change to black. Also, the majority of birds so change their color in accord with the seasons that a person unfamiliar with them would not recognize them. **519ª1**

Some animals change the color of their hair in accord with changes in the waters; for the same sorts are white in one place, black in another. Also, as regards mating, the waters are in many places of such a sort that if rams mate after drinking it they beget black lambs—for example, in the district of Assyritis in the Chalcidian peninsula in Thrace the river called the "Cold" produced this effect. In Antandria too there are two rivers, one of which makes sheep white, the other black. It also seems that the river Scamander makes sheep yellow (*xantha*); that is why, they say, instead of "Scamander," Homer calls it the "Xanthus."[139]

The other animals do not have hair internally, and on the extremities have it on the upper surface, not on the underneath parts; the hare alone has hair both inside its jaws and on the underside of its feet. Further, the *mustokêtos*[140] does not have teeth in its mouth, but hairs like pigs' bristles.

Hairs that have been cut grow from below, not from above. Feathers, by contrast, grow neither from above nor from below, but fall out. The wing of the bee will not grow back when it is plucked out, nor will that of any other animal with an unsplit wing; nor will the sting, when the bee loses it; instead, the bee dies.

3.13
Membrane

There are membranes too in all blooded animals. The membrane is like dense, fine-grained skin, but it is of a different kind; for it is neither splittable nor stretchable. There is membrane around each of the bones and around each of the viscera, both

139. *Iliad* 20.74.
140. Reading μυστόκητος ("mouse-whale").

in the large and in the small animals; but they are invisible in the very small ones,
519b1 because they are altogether fine-textured and small.

The largest membranes are the two around the brain:[141] the one around the bone is stronger and thicker than the one around the brain itself; next is the membrane around the heart. A bare membrane, once cut, does not grow back together; bones bared of membranes become gangrenous.

3.14
The Omentum

The omentum is also a membrane. All the blooded animals have an omentum; in some it is fatty, in others it is without fat. Its starting-point and its point of attachment in the live-bearing animals that have two rows of teeth is in the middle of the stomach, where there is a sort of suture in the stomach; in those that do not have two rows of teeth it is in the large stomach in the same way.

3.15
The Bladder

The bladder too is membranous, but is of a different kind than membrane; for it has elasticity. Not all animals have a bladder; all the live-bearing ones do, but among the egg-laying ones only the turtle does. The bladder, once cut, does not grow back together again, unless the cut is at the starting-point of the urethra, except altogether rarely; for something of this sort has been observed to occur. In dead animals no liquid [residue] is passed through it; in living animals, solid compositions also are, from which stones come to be in those who suffer from them. In some people compositions of this sort have been observed in the bladder that seem not to differ at all from shellfishes.

———

As regards blood vessel, sinew, and skin, as well as fibers and membranes, then, and as regards hair, nail, claw, hoof horn, teeth, beak, cartilage, bones, and their analogs, these are the ways they are.

3.16
Flesh

Flesh and what has much the same nature as flesh is present in the blooded animals—in all cases between the skin and the bone or the parts analogous to the bones; for

141. The meninges (514a17).

as spine (in those that have spine) is to bone (in those that have bones) so what is flesh-like is to the flesh.

Flesh is divisible in every way, not lengthwise only, like the sinews and the blood vessels. When animals become thin, the flesh disappears, and the blood vessels and fibers become [apparent]; when they are abundantly fed, fat replaces flesh. In animals having a lot of flesh, the blood vessels are smaller, the blood redder, and the intestines and stomach small. In those that have large blood vessels, the blood is blacker, the intestines large, and the stomach large, and the quantity of flesh smaller. Animals that have small stomachs become fat in their fleshy parts. **520^{a}1**

3.17
Fat and Suet (1)

Fat and suet differ from each other. For suet is shatterable in every way and solidifies when made cold, while fat is liquefiable but not solidifiable. Soups made from fatty meats—for example, those of the horse and the pig—do not solidify, while those made from meats that have suet—for example, those of the sheep and the goat—do solidify. They also differ in their places; for fat occurs between the skin and the flesh, while suet does not occur there but at the ends of the fleshy parts. The omentum in fatty animals is fatty, and in suety animals is suety. Animals that have two rows of teeth have fat. Those that do not have two rows have suet.

Among the viscera, the liver in some animals becomes fatty—for example, among the fishes, the selachians; for an oil is produced from these when they become melted. The selachians themselves are not fatty at all, having no separated fat against their flesh or their stomach. The suet in the fishes too is fatty and does not solidify.

All animals have fat, some against their flesh, some separately. Those who do not have separated fat are less fatty than others in stomach and omentum—for example, the eel; for it has little fat around the omentum. Most animals become fat in the abdomen, especially the animals that are not [much] in movement.

The brains of fatty animals are oily[142]—for example, the pig; those of suety animals are dry [of oil].

Among the viscera, it is around the kidneys that animals most become fat; the right kidney is always less fatty than the left; and if both are very fat, there is always a gap between them that is fatless. It is around the kidneys that suety animals most become suety, and most of all the animals, the sheep; for it dies when its kidneys are on every side covered by suet. The kidneys become covered due to abundant feeding, as in the region of Sicily around Leontini; that is why they do not drive the sheep out to feed until late in the day, in order to reduce the nourishment they take. **520^{b}1**

142. *PA* 652^{a}24–33.

3.18
Fat and Suet (2)

Common among all animals is the part of the eye around the eye-jelly;[143] this part is, in fact, suety in all the ones that have eye-jelly in their eyes and are not hard-eyed.[144]

All fatty animals, both male and female, are less fertile.[145]

All animals fatten more when older than when younger, and do so most when they achieve their [proper] magnitude in breadth and length but grow in depth.

3.19
Blood and Serum

As regards the blood, it is the following way. It is the most necessary and the most common part in all the blooded animals; it is not something acquired later, but is present in all those that have not passed away. All blood is in a vessel, which are called "blood vessels," and nowhere else except in the heart alone. Blood has no perception in any of the animals when they are touched, any more than the residue in the stomach does. The brain and the marrow have no perception of being touched either. Wherever the flesh is cut in a living animal, blood is produced, provided the flesh is not corrupted. It is the nature of blood to have a sweet flavor and a red color, if it is in a healthy condition. But if it is in a lesser one, either by nature or due to disease, it is blacker. The best blood is neither very coarse-grained nor very fine-grained, unless it is in a lesser condition either due to nature or due to disease. Inside a living animal, it is always liquid and hot, but on going outside the blood of all animals solidifies, except for the deer, the roe deer, and other animals that have this sort of nature. All other blood solidifies, unless the fibers are removed. The fastest of all to solidify is the blood of the bull.

Among the blooded animals, those that are both internally and externally live-bearing have more abundant blood than the blooded egg-laying animals. Animals that are in good condition, either by nature or by being [kept] healthy, do not have too much blood, like those that have recently been drinking do, nor too little, like animals that are too fat; for fat ones have blood that is pure but little in quantity, and the fatter they become the less blood they have; for fat is bloodless. Fat does not
521ᵃ1 putrefy, but the blood and the blooded parts putrefy most quickly, and among these parts, the parts around the bones.

It is the human being that has the most fine-grained and purest blood, and, among the live-bearing animals, the bull and the ass have the most coarse-grained and the

143. The white of the eye.
144. *PA* 657ᵇ29–658ᵃ3.
145. *GA* 726ᵃ3–6.

blackest. In the lower parts of the body the blood is more coarse-grained and blacker than in the upper parts.

The blood in the animals beats at the same time in all the blood vessels in every part. And the blood alone is the only liquid in the animals that is present throughout the entire body and always, for as long as they live. The blood in the animals comes about first in the heart, even before the body as a whole becomes articulated. If they have blood taken or if it is emitted in a relatively large quantity, animals faint; if the quantity is too large, they die. If the blood is too liquid, animals fall ill; for it becomes like serum—in fact it becomes so serum-like that cases have been observed of people sweating a bloodlike sweat. In some cases, when the blood goes out, it does not solidify at all, or only in distinct and separate places. In those who are asleep, the blood in the outside parts is smaller in quantity [than when they are awake], so that if they are pricked, it does not flow to the same extent.

Blood is produced by concoction from serum, and from blood fat. Diseased blood produces hemorrhoids in the nostrils and around the fundament, also varicose veins. Blood that putrefies in the body becomes pus, and from pus a solid mass develops.

The blood of females differs from that of males; for it is coarser-grained and darker in females of similar health and age to males, and though there is less on the surface in females, on the inside they have more abundant blood. Among female animals, it is the woman that has the most abundant blood, and the so-called menses are largest in quantity in women among all animals. This blood, when it is diseased, is called "flux." Women share less in these diseases than men; for few women get varicose veins, hemorrhoids, or nosebleeds; but if any of them do occur, the menses are lesser.[146]

Blood also differs in quantity and quality with age; for in altogether young animals it is serum-like and greater in quantity; in old ones it is coarse-grained, black, and small in quantity; in those in their prime it is in the mean. The blood of aged animals solidifies quickly, even if it is on the surface of the body; in the young ones this does not occur. **$521^{b}1$**

Serum is unconcocted blood; either blood that is not yet concocted or that has become serum-like.

3.20
Marrow and Milk (1)

Next is marrow; for it too is among the liquids that exist in certain blooded animals. All the liquids that by nature exist in the body are in vessels, just as blood is in blood vessels, marrow in bones, and others are in membranes, skins, or cavities.

In young animals the marrow is altogether bloodlike; among older ones, that of fatty animals becomes fatty, that of suety ones suety. Not all bones have marrow, but

146. $587^{b}32–34$.

only the hollow ones, and even in some of these it is not present; for among the bones of the lion, some have none altogether, while others have little. That is why some people say that lions have no marrow at all, as was said previously.[147] And in the bones of pigs there is little, though in some of them there is none altogether.

The liquids we mentioned are pretty much always innate in the animals, though milk and semen are produced after birth. Of these, milk, when it is present, is in all cases produced as a secretion; but semen is not produced in this way in all animals, but rather so-called seminal fluids are produced in certain ones—for example, the fishes.

All the animals that have milk have it in the breasts. All animals that are both internally and externally live-bearing have breasts—for example, all the ones that have hair, such as the human being and the horse; and also the cetaceans—for example, the dolphin, the porpoise, and the whale; for these also have breasts and milk. Those that are externally live-bearing only, or that are egg-laying, do not have either breasts or milk—for example, the fishes and the birds.

All milk contains a watery serum, which is called "whey," and a corporeal part, which is called "curd"; the more coarse-grained the milk, the more curd it has. The milk of the animals that do not have two rows of teeth solidifies (that is why the milk of the tame ones is made into cheese), but that of the ones with two rows of teeth does not solidify, any more than their fat does, and is fine-grained and sweet. The finest-grained of all milk is the camel's, second, that of the horse, third, that of the ass; the coarsest-grained is that of the cow. Milk does not solidify due to the cold, but becomes more serum-like; on the fire, though, it solidifies and becomes coarse-grained.

For the most part, milk is not produced in any animal until pregnancy. But when the animal is pregnant, it is produced; the first milk is unusable and later on is so again. In non-pregnant animals, a small quantity of milk is produced due to certain foods; and, indeed, cases have been observed of elderly women who, on being milked, produce some, and in certain cases enough to suckle a baby.

The people around Mount Oeta take female goats that refuse to mate and forcibly rub their udders with nettles, because that is painful. What is squeezed out is first bloodlike, then mixed with pus, and finally milk that is no less in quality than from those that were mated.

For the most part, milk is not produced in any males, either in the other animals or in the human being. Nonetheless, it is produced in some cases; thus in Lemnos, from the breasts of a male goat, of which he had two near the sex organ, milk was squeezed in sufficient quantities to make cheese; and again, after mating, the same thing occurred in the male as a result of mating. But things of this sort are regarded as signs; thus, to the man in Lemnos the god responded by prophesying that he would gain further possessions. In certain men, after puberty, a small quantity of milk can

147. 516b7–9.

be squeezed out; and from some, when milked, large quantities have been observed to come out.

Milk has in it a fatty element; in milk that has solidified it even becomes oily. People mix goats' milk into sheep's milk in Sicily, and wherever it is fat.[148] The milk that solidifies most is not only that which has the most cheese, but also that in which the cheese is drier [of fat].

Some animals have more milk than is needed for the nourishment of their offspring, and this is useful for cheesemaking and for storage, especially goats' milk and sheep's milk, then cows' milk. Horses' milk and asses' milk are mixed together to make Phrygian cheese. There is more cheese in cows' milk than in goats' milk; for herdsmen say that from one amphora of goats' milk they can get nineteen one-obol cheeses, but thirty from cows' milk.

Other animals have only enough milk for their offspring, and none has abundant milk or milk useful for cheesemaking—for example, those with more than two breasts; for none of these has abundant milk nor is the milk made into cheese. **$522^{b}1$**

Milk is curdled by fig juice and rennet. The fig juice is squeezed out into wool. When the wool is rinsed again, it is put into a little milk; for this milk, when mixed in, causes milk to curdle. Rennet, for its part, is milk; for in the case of animals that are still being suckled, it is produced in their stomach.

3.21
Rennet and Milk (2)

Rennet, then, is milk that contains the fire that comes from the heat of the animal when the milk is being concocted [in the stomach]. All ruminants have rennet and, among those with two rows of teeth, the hare. Rennet is better the older it is; this sort is mostly advantageous for diarrhea, as is that of the hare; but best is that of the faun.

There is difference of the more or less in the milk yielded by the animals that have milk, which is in accord with the size of their bodies and the differences in their foods—for example, there are small cows in Phasis each of which produces a lot of milk, and large ones in Epirus each yield an amphora and a half from their two breasts (the milker stands upright, bending forward a little, because he would not be able to reach them when seated). But, apart from the ass, all the four-footed animals in Epirus are large, and the largest are the cows and the dogs. Large animals need more pasture; but this land has a lot of abundant feeding of this sort and places suitable for it in each season. The very large cows and sheep are called "Pyrrhic," taking this name from King Pyrrhus.

148. Reading πῖον.

Some nourishment dries up the milk—for example, Median grass,[149] especially in ruminants. Other sorts produce more—for example, cytisus and bitter vetches, except that cytisus when in bloom is not advantageous (for it burns), and for pregnant animals bitter vetches are not advantageous (for they make giving birth more difficult). In general, just as those four-footed animals that are able to eat [well] are advantaged with regard to pregnancy, so they produce a lot of milk when they have [good] nourishment. Some of the foods that produce wind also produce milk—for example, a large quantity of beans for the sheep, the goat, the cow, and the small goat; **523ᵃ1** for they lengthen the udder. A sign of yielding a lot of milk is when the udder faces downward before giving birth. Milk is produced for a long time in all those animals that have it, if they are not mated and have suitable foods; most of all, among four-footed animals, the sheep; for it can be milked for eight months.

In general, the ruminants yield a lot of milk and it is useful for cheesemaking. Around Torone, the cows leave an interval of a few days before giving birth, but all the rest of the time have milk. In women, milk of a more blue-tinged color is better than white milk for suckling infants; and the milk of dark-skinned women is healthier than that of pale women. The most nourishing milk is that which contains the most cheese, but milk that contains less is healthier for little children.

3.22
Seed

All blooded animals emit seed.[150] What it contributes to generation and how it does so will be discussed elsewhere.[151] In proportion to [size of] body, the human being emits the most seed. It is viscous in animals that have hair, but in others it does not have viscosity. It is white in all of them: Herodotus is mistaken when he writes[152] that Ethiopians emit black semen.

Seed is white and coarse-grained when it emerges, if it is healthy; but when it is outside, it becomes fine-grained and black. In times of frost, it does not solidify but becomes altogether fine-grained and watery both in color and consistency; due to heat, it solidifies and becomes coarse-grained. When it remains in the uterus for a time, it emerges coarser-grained and, sometimes, dry and compact. The fertile sort sinks to the bottom in water. The infertile sort dissolves. What Ctesias wrote[153] about the semen of elephants is false too.

149. Probably alfalfa (*Medicago sativa*).

BOOK 4

4.1
Bloodless Animals: Soft-Bodied Animals

As regards the blooded animals, then, what parts they have in common and what ones are special to each kind, both the non-uniform ones and the uniform ones, both external and internal, was stated previously. The bloodless ones must now be spoken about.

There are many kinds of these. One is that of the so-called soft-bodied animals. **$523^{b}1$** These are all the ones which, being bloodless, have their fleshy part outside, and their solid part, if any, inside, as in the case of the blooded animals—for example, the cuttlefish kind.

Another one is that of the soft-shelled animals. These are all the ones that have the 5 solid part outside and the soft fleshy part inside; the hard part of these is not receptive of impressions but is shatterable;[154] the crayfish kind, for example, and the crab kind are of this sort.

Further, there are the hard-shelled animals. Of this sort are those that have their fleshy part inside and their solid part—which is shatterable and breakable, but not 10 receptive of impressions—outside. The snail kind and that of the shellfishes are of this sort.

The fourth kind is the insect kind, which includes many dissimilar forms of animals. The insects are all the animals that, as their name implies, have either their underneath parts, back parts, or both in sections, and do not have either a separate bony part or fleshy part, but something intermediate between the two; for their 15 body is similarly hard both on the inside and outside. There are wingless insects (for example, the centipede and the millipede) and winged ones (for example, the bee, the cockchafer, and the wasp); and the same kind is in some cases both winged and wingless (for example, the ant is both winged and wingless, and the so-called 20 glowworm too).

The external parts of the so-called soft-bodied animals are as follows: first, the so-called feet; second, continuous with these, the head; third, the cavity, which encompasses the internal parts, and which some people—wrongly—call the head; and further, the fins, which are in a circle around the cavity. 25

In all soft-bodied animals the head is between the feet and the abdomen. All of them have eight feet, and all of these have a double row of suckers, except in the case of one kind of octopus.[155] A special affection of the cuttlefishes, the small calamary, and the large calamary is that they have two long proboscises, having two rows of 30

154. *Mete.* 4.8–9.
155. $525^{a}16–20$.

suckers on a roughness at the extremities, with which they grasp their nourishment and bring it to their mouth, and when the weather is stormy, they throw them around a rock like anchors, and ride out the storm. With their fins, which they have around
524ᵃ1 the cavity, they swim. On the feet of all of them there are suckers.

The octopus uses its tentacles both as feet and as hands. It brings in [nourishment] with the two that are above its mouth. The last tentacle, which is most sharp and is
5 the only one that is whitish in color and divided in two at the extremity (this division goes to the rachis; "rachis" is what the smooth part is called that is further out from where the suckers are), this is the tentacle it uses in mating.[156] In front of the cavity and above the tentacles they have a hollow funnel through which they emit from the
10 cavity any seawater they may have taken in when they are taking some [nourishment] into their mouth. The octopus turns this about, sometimes to the left, sometimes to the right, and it is with this that it emits its ink.

The octopus swims obliquely, in the direction of the so-called head, by extending its feet; in this way of swimming it can look forward (for its eyes are on the upper
15 side); it has its mouth at the rear. While it is alive, its head is hard, as if it were inflated. It touches and holds its prey with the underneath parts of the tentacles, and the membrane that is between its feet is kept fully extended; but if it falls on the sand, it can no longer hold it.

20 The octopuses and the other soft-bodied animals mentioned exhibit a difference; for the cavity of the octopuses is small and the feet long, while among the others, the cavity is large and the feet short, so that they cannot move by walking on them. In comparison to each other, the calamary is longer and the cuttlefish is broader.
25 Among the calamaries, the so-called large calamaries are much longer; for some reach five cubits in length. Some cuttlefishes too reach two cubits; and the tentacles of the octopus can be as long as this, or even longer. The large calamary kind is few in number. The large calamary differs from the small calamaries in shape: the sharp part
30 of the large calamaries is broader. Further, the circle of its fins goes all around the cavity; in the small calamary it has a gap. The large calamary is a deep-sea dweller, like the small calamary.

In all cases the head comes after the feet, in the middle of the feet or "tentacles," as
524ᵇ1 they are called. Of this one part is the mouth, in which there are two teeth; above it are two large eyes, between which is a small cartilage containing a small brain. Inside
5 the mouth is a small fleshy part; none of them has a tongue, but this part is used in place of a tongue.

After this, on the outside, can be seen what appears to be a cavity. The flesh of this can be split, not lengthwise but in a circle. All the soft-bodied animals have skin around this part. After the mouth they have an esophagus that is long and narrow,
10 and, following it, a crop that is large and round, like a bird's. This is followed by the stomach, like the abomasum; its shape is like the spiral in trumpet shells. From this

156. *GA* 720ᵇ32–36.

a thin intestine goes back again toward the mouth: this intestine is thicker than the esophagus.

None of the soft-bodied animals has viscera, but only what is called a *mutis*, and on it is the ink sac. The cuttlefish has the most ink and the largest sac. All of them emit ink when they are frightened, especially the cuttlefish. The *mutis* is situated under the mouth, and through it the esophagus extends. Below the point where the intestine extends upward is the ink sac, which is encompassed by the same membrane as the intestine, and through the same duct emits both the ink and the residues. These animals have certain hair-like growths[157] on the body.

In the cuttlefish, the small calamary, and the large calamary, the solid parts are in the inside, toward the back of the body; they are called the "sepium" and the "sword." But there is a difference: sepium is strong and broad, intermediate between spine and bone, and has in it a crumbly spongy material; in the calamaries it is fine-grained and cartilaginous. They differ from each other in shape, as do their cavities. The octopuses do not have any solid part of this sort inside, but cartilage around the head, which becomes hard if the animal gets older.

The females differ from the males; for the males have a duct below the esophagus, extending from the brain to the lower part of the cavity; and the part it extends to is similar to a breast. In the females, by contrast, there are two of these parts situated higher up. In both sexes, below these parts, there are also certain small red corpuscles. **525^{a}1**

The egg[158] of the octopus is a single one, irregular on the outside, and large; inside, the liquid is all single-colored and smooth, its color is white. The magnitude of the egg is so great that it fills a vessel larger than the octopus' head. The cuttlefish has two cavities with a lot of eggs in them, similar to white hailstones. The situation of each of these parts must be observed in the diagram in the *Dissections*.

In the case of all these animals, the males differ from the females, especially the cuttlefish; for the back of the cavity, which is blacker than the underneath part, is rougher in the male than in the female; and the male's back is variegated with stripes and the rump more pointed.

There are many kinds of octopuses. The first is the one that keeps most close to the surface and is the largest of them (the ones that keep inshore are much larger than the deep-sea ones); and further, there are others, small variegated ones, and not for eating. There are two others, one called *heledônê*, which differs in the length of its feet and in being the only soft-bodied animal with one row of suckers (all the rest have two rows), and the other, the one sometimes called *bolitaina*, sometimes *ozolis*.[159] There are two others that live in shells. One is called by some people the "nautilus" or "pontilus," by others the "octopus' egg." Its shell is like a valve of a detached deep scallop shell. This one often lives near the land, and sometimes gets washed ashore by

157. Probably the gills.

158. The egg-mass.

159. $621^{b}17$. The names mean "onion" and "smelly." Probably, *Eledone moschata*.

the waves; when its shell falls away, it is stranded, and dies on the land. These animals are small; their appearance is like that of the *bolitaina*. And there is another that lives in a shell like a snail; it does not emerge from its shell, but stays inside like a snail, and sometimes puts out its tentacles.

The soft-bodied animals have now been spoken about.

4.2
Soft-Shelled Animals

Among the soft-shelled animals, one kind is that of the crayfishes, and another much the same as this is that of the so-called lobsters; these differ from the crayfishes in having [large] claws; the other sorts of differences are not numerous. Another one is that of the carids,[160] and another that of the crabs.

There are many kinds of carids and of crabs. Among the carids are the hunchbacks, **525b1** the *kraggôn*,[161] and the small kind (for these never become larger). The kinds of crabs are multifarious and not easy to enumerate. The largest is the one they call *maia*; second are the *pagouroi*,[162] the Heracleotic crabs,[163] and further, the river crabs. The others are smaller and more often nameless. In Phoenicia, crabs occur on the beaches that are called "horses," because they run so fast that it is not easy to catch them; when they are opened up, they are empty because of not having food to eat. There is also another small kind like the crabs, but its appearance is like that of the lobsters.

All these animals, as was said previously, have the solid shell-like part on the outside in place of the skin, and the fleshy part inside; the underneath parts are more laminar: this is where the females lay their eggs.

The crayfish have five feet on each side with claws at the extremities; likewise, the crabs have ten feet in total, including the claws. Among the carids, the *kuphai* have five feet on each side, with those toward the head being sharp-pointed, and five more on either side on the abdomen, the extremities of which are broad. They have no flaps on the underneath parts, but their back parts are like those of the crayfishes. It is contrariwise with the *kraggôn*: it has four primary feet on either side, then three thin ones next to them on either side; the remaining larger part of the body is footless. All these animals bend their feet obliquely like the insects; the claws, in those that have claws, bend inward. The crayfish has a tail too and five fins; the hunchback has a tail and four fins; the *kraggôn* also has fins on each side of the tail. The middle part of the tail of both the hunchback and the *kraggôn* is spinous, though in the latter it is broad, in the hunchback it is pointed. The crab alone among these sorts of animal

160. Small soft-shelled animals other than crabs or lobsters.
161. Squillae.
162. Probably the common edible crab.
163. *PA* 684a10.

does not have a tail; and while the body of the carids and the crayfishes is elongated, that of the crab is round.

The male crayfish differs from the female; for in the female the primary foot is divided, while in the male it is undivided; the fins on the underneath part in the **526ª1** female are large and overlap near the neck, while in the male they are smaller and do not overlap. Further, in the male there are large sharp projections like spurs on the last feet, while in the female these are small and smooth. Both sexes alike have two 5 antennas in front of the eyes that are large and rough, and other small antennas below that are smooth.

The eyes of all these animals are hard and move to the outer side, the inner side, and obliquely. It is likewise in most of the crabs—even more so. 10

The lobster has an all-over whitish color, sprinkled with black. Its under-feet, up to the large ones, are eight in number, and after them come the large ones, which are much larger and broader at the extremities than those of the crayfish, and unlike each other; for in the right one the broad extremity is elongated and thin, while in the left 15 one it is thick and rounded. At the extremity each is divided like a jaw that has teeth above and below, except that in the right one they are all small and saw-like, while in the right one, though they are saw-like at the extremity, those on the inside are like molars, in the lower part of it there are four joined together, and in the upper there 20 are three and they are not joined together. In both the upper part moves and presses hard against the lower part. Both are set like bandy legs, as is natural for grasping and pressing hard. Above the large ones there are two other hairy ones, a little below 25 the mouth, and underneath these are the gill-like parts around the mouth, which are hairy and numerous. The animal always keeps these in movement; it bends the two hairy feet and draws them in toward the mouth. The feet near the mouth also have thin appendages.

The lobster has two teeth,[164] like the crayfish, and above them are the antennas, 30 which are long, but shorter and much thinner than those of the crayfish, and it has four others similar in shape to these, but shorter and thinner. Above these are the eyes, small and short,[165] not large like those of the crayfish. The sharp and rough part **526ᵇ1** above the eyes, just like a forehead, is larger than that of the crayfish. In general, the facial part is more pointed and the thorax much broader than in the crayfish, and the whole body fleshier and softer. Of the eight feet, four are divided in two at the 5 extremity and four are not. The region around the so-called neck is divided externally into five parts; a sixth one is the broad region at the extremity, which has five flaps; the inner parts, where the females lay their eggs, are four in number and hairy. On 10 each of the parts mentioned the lobster has, pointing outward, a spine that is short and straight. The whole body and the parts around the thorax are smooth, not rough as in the crayfish; but the large feet have on the outside larger spines. Between the

164. Mandibles.
165. I.e., less projecting.

female and the male there is no apparent difference; for in fact both the male and the female have one claw (whichever it happens to be) larger than the other, but neither sex ever has both of equal size.

Seawater is taken in by a part beside the mouth in all animals of this sort; the crabs, having taken it in,[166] emit it by closing up this part a little; the crayfishes emit it beside their gill-like parts; the crayfishes have many gill-like parts.

Common to all these animals are the following: they all have two teeth (for even the crayfishes have two primary ones), and in the mouth they have a part more fleshy [than these] in place of a tongue; then they have a stomach right next to the mouth, except that the crayfishes have a small esophagus in front of the stomach, then from the stomach there is a straight intestine. This extends, in the crayfish-like animals and the carids, in a straight line to the tail, where they emit the residues and lay the eggs; but in the crabs, it is where they have the flap, and the middle of the flap is where they lay the eggs (for they also lay them outside). Further, the females of these have near the intestine the place for the eggs. And they all have, more or less, the so-called *mutis*, or *mêkôn*.

But the special differences of each of these animals must also be observed.

527ᵃ1 The crayfishes, then, as was said, have two teeth, which are large and hollow, in which there is a humor similar to the *mutis*, and between the teeth a fleshy part that is tongue-shaped. After the mouth there is a short esophagus, and following it a stomach that is membranous, and by its orifice there are three teeth, two of them opposite each other and one below. Coming from the side of the stomach is an intestine that is simple and of equal thickness throughout its whole length until it reaches the outlet for the residue. The crayfishes, the carids, and the crabs all have these parts; for the crabs also have two teeth.

Further, the crayfishes have a duct attached going from the chest to the outlet for the residue. In the female this serves as a uterus, in the male as a duct for the seminal fluid. This duct is attached to the concave surface of the flesh in such a way that the flesh has an intermediate position; for the intestine is situated on the convex side, the duct on the concave, similar to the way they are in the four-footed animals. That of the male is no different from that of the female; for in both it is thin, white, and contains a yellow liquid, and further, both are attached to the chest.

This is also the way the egg and the spirals[167] are in the carids. The male has a special affection in comparison to the female: in the flesh that is on its chest it has two white parts, each by itself, that in color and consistency are like the proboscises of the cuttlefish, and spiral like the *mêkôn* in the trumpet-shell. The starting-point of these is in the cotyledons, which are under the last of the feet. In this place the flesh is red and bloodlike in color, but viscous to the touch and not like the flesh. From the trumpet-shell-like part on the chest there is another spiral, like string in

166. Reading ἐπιλαμβάνοντες.
167. *PA* 680ᵃ22.

thickness. Below these parts there are two crumbly ones attached to the intestine that are seminal. These, then, are the parts in the male. The female has eggs, red in color, that are attached to the stomach and to each side of the intestine as far as the fleshy part; these are encompassed by a thin membrane.

These, then, are all the internal and external parts of these animals.

4.3[168]
Crabs

The internal parts of the blooded animals happen to have names; for all these have the internal viscera. On the other hand, none of bloodless animals does, though common to these and all the blooded animals are the stomach, the esophagus, and the intestine. **527^b1**

As for the crabs, as regards the claws and feet, that they have them and the way they have, was stated previously.[169] For the most part, all have the right claw larger and stronger than the left. As regards the eyes, it was also said previously[170] that in most of them they look to the side. The trunk of the body is an undivided unit, which includes[171] the head and any other part (if there is one). Some of them have eyes on the upper side immediately below the back and very far apart; others have them in the middle and close together—for example, Heracleotic crabs and the *maia*.[172] The mouth is below the eyes, and in it are two teeth, as in the crayfish, except that they are not round but long. Over the teeth there are two lids, and between these are some entities like the ones the crayfish has beside its teeth. The crab takes in water beside its mouth, pushing it away with the lids, and discharging it through the upper ducts of the mouth, while closing with the lids the orifice from where it came in. These ducts are immediately under the eyes; and when it takes in the water, it closes its mouth with the two lids and in this way spews out the seawater.

Following the teeth is the esophagus, which is altogether short, so that it seems that the stomach comes immediately after the mouth. The stomach that follows the esophagus is divided in two, and coming from the middle is the intestine, which is simple and thin; the intestine ends under the exterior lid, as was said previously.[173] {Between the lids it has some entities like the ones the crayfish has beside its teeth.}[174]

168. This chapter mostly repeats what has already been said, and contains some sentences, enclosed in curly brackets, that seem to be glosses.

173. $526^b26–30$.
174. Secluded as a near repetition of 527^b16.

Inside the trunk is a yellow humor, small parts that are elongated and white, and other ones that are sprinkled with red.

The male differs from the female in size, in breadth, and in the lid; for in the female this is larger, stands out more, and is more thickly covered [with hair],[175] just as in the case of the female crayfishes.

———

These, then, are the ways the parts of the soft-shelled animals are.

4.4
Testaceans

The hard-shelled animals—for example, the land snails, sea snails, all the so-called **528a1** shellfishes, and further, the urchin kind—have the fleshy part (in the ones that have flesh) in the same way as in the soft-shelled animals (for they have it inside), but the shell outside, and there is no hard part inside. Compared with one to another, these animals exhibit many differences, both with respect to their shells and with respect to the flesh within.

For some of these have no flesh at all—for example, the urchin; others have it, but it is all inside and invisible, except for the head—for example, the land snails and the *kokalia*, as they are called by some people, and, among sea animals, the purpura, the trumpet-shell, the sea snail, and the other spiral-shelled animals. Among the others, some are bivalves, others univalves; by "bivalves" I mean those that are encompassed by two shells, by "univalves" those that are encompassed by one. In the latter, the fleshy part is exposed—for example, the limpet. Among the bivalves, some can open—for example, the scallop and the mussel; for all animals of this sort are joined on one side and parted on the other, so that they can close and open. Some, though bivalves, close equally on both sides—for example, the razor fish. Some are wholly encompassed by their shell and no part of their flesh is bare on the outside—for example, the so-called sea squirts.

Further, their shells themselves exhibit differences from each other. For some have smooth shells—for example, the razor fish, the mussel, and some of the clams (the ones that some people call "milk shells"); others have rough shells—for example, lagoon oysters, pinnas, some kinds of clams, and the trumpet-shells; and among these, some have ribbed shells (for example, the scallop and a kind of clam), while others are ribless (for example, the pinna and another kind of clam).

They also differ in the thickness and thinness of their shells, whether in the whole shell or with respect to a part—for example, the lips; for some have thin-lipped shells (for example, the mussels), while others have thick-lipped ones (for example, the lagoon oysters). Further, some of them are mobile—for example, the scallop (in fact

175. 541b30.

some people say that scallops can fly, since in fact they often jump out of the instrument with which they are caught); others cannot move from what they are attached to—for example, the pinna. All the spiral-shelled animals move and creep; even the limpet releases itself to feed. Common to these and to the other hard-shelled animals **528^{b}1** is that the shell has a smooth interior.

In the univalves and the bivalves, the fleshy part is so attached to the shells that it is detached [only] by force; in the spiral-shelled animals it is more easily detached. Special to all the latter as regards the shell is the spiral that belongs to the extremity of 5 the shell furthest from the head. Further, all of them from birth have an operculum. Further,[176] all the hard-spiral-shelled animals have the shell on the right side, and they move not in the direction of the spiral, but in the opposite direction.

These, then, are the differences exhibited by the external parts of these sorts of 10 animals.

As for the internal parts, they have a nature that is in a way much the same, especially the spiral-shelled animals (for these differ from each other in size and with respect to excess [and deficiency] in their affections); nor do most[177] of the univalves and bivalves differ much. For they exhibit but little difference in relation to each 15 other, but much more in relation to the ones that are immobile. This will be more evident later on.[178]

The nature of all the spiral-shelled animals is the same, differing, as was said, with respect to excess [and deficiency] (for the larger ones have larger and more clearly perceptible parts, while the smaller have the opposite), and further, in hardness and softness, and other affections of this sort. For the fleshy part, which they all have at the 20 outermost part of the mouth of the shell, is firm—more so in some, less so in others. From the middle of this come the head and the two horns: these horns are large in the larger ones and altogether small in the smaller ones. In all of them the head emerges 25 in the same way; and if the animal is frightened, it draws it inside again. Some of them, like the snail, have a mouth and teeth that are small and thin. They also have a proboscis, as flies also do, which is tongue-shaped. The trumpet-shells and the murex also have one that is firm, and, just as the horsefly and the gadfly pierce the skins of 30 the four-footed animals, its strength is yet more forceful; for they pierce the shells of the bait used to capture them.[179] The stomach comes immediately after the mouth. The stomach of the snail is like a bird's crop. Underneath, it has two firm white **529^{a}1** entities, like breasts, of the sort that also appear in the cuttlefish, except that there they are firmer. From the stomach a simple long esophagus extends as far as the *mêkôn*, which is in the base [of the shell]. All these parts are clear to perception both 5 in the purpuras and the trumpet-shells and are in the spiral of the shell.

176. Reading ἔτι.
177. Reading τὰ πλεῖστα.
178. The reference may be to *PA* 4.7.
179. *PA* 661^{b}21.

Following the esophagus there is the intestine (the esophagus and the intestine are continuous), which is entirely simple up to the outlet [for the residue]. The starting-point of the intestine is around the spiral of the *mêkôn*, and there it is broader (for much of the *mêkôn* is a sort of residue in all of the shelled animals), then bending and going upward again toward the fleshy part, the intestine ends near the head, where it emits the residue; it is likewise in all the spiral-shelled animals, both terrestrial and marine. In the large snails, woven along the esophagus from the stomach, there is a long white duct enclosed in a membrane, similar in color to the breast-like formations above. It has sections, like the egg of the crayfish, except that its color is white, while the latter's is red. It has no outlet or duct at all but is inside a thin membrane, with a narrow cavity inside it. From the intestine downward black rough entities extend in a continuous line, like those in the turtle, except less black. The sea snails also have these and the white entities, except that they are smaller in the smaller ones.

The univalves and bivalves are in some respects similar to the spiral-shelled animals and in some respects dissimilar. For they have a head, horns, mouth, and the tongue-shaped part; but in the smaller ones these are invisible because of their smallness in size; even in dead animals or ones that are not moving some of them are invisible. All of them have the *mêkôn*, although not all in the same place, or of the same size, or equally visible: the limpets have it below in the depths [of the shell], while the bivalve have it in hinge-like part. They all have the hair-like growths too, in a circular pattern, as, for example, in the scallops. The so-called egg in those that have it, when they have it, is situated on one of the semicircles of their circumference and is like the white entity in the snails; for these two things are the same.

But all these parts, as was said, while clear to perception in the larger animals, in the smaller ones are not at all clear or scarcely so. That is why they are especially visible in the large scallops: these are the ones that have one of the two valves flat-shaped, like the lid of a pot. The outlet for the residue in the others[180] is on the side; for there is a duct for it to come out; for the *mêkôn*, as was said,[181] is in all of them a residue inside a membrane. The so-called egg does not have a duct in any of them, but is a swelling up of the flesh itself. And it is not on the same side as the intestine: instead, the egg is on the right, the intestine on the left. This is the way the outlet for the residue is in the others, but in the wild limpet, which some people call a "sea ear," the residue emerges under the shell; for the shell is perforated. In this animal, both the stomach coming after the mouth and the egg-like formations are visible. The way that all these parts are situated must be observed with the help of the *Dissections*.

The so-called hermit crab in a way has something in common with both the soft-shelled and the hard-shelled animals. For, in its nature, it is like the crayfish-like animals, and it is born by itself,[182] but by entering into a shell and living there it

180. Besides the wild limpet (529b14–17).
181. 529a11–12.
182. I.e., without a shell.

becomes like the soft-shelled animals, so that because of these things it seems to play a double game. Its shape, to put it simply, is like that of the spiders, except that the part below the head and the thorax is larger than those [of spiders]. It has two small horns, thin and red, and under them two long eyes, which do not go in or turn sideways, like those of the crabs, but stick straight out. Under these is the mouth, and around it a lot of hair-like growths. Following these are two feet divided in two, with which it draws things toward itself, then two others on either side, and a third small one. The entire part below the thorax is soft and, when opened up, is yellow inside. From the mouth **530^{a}1** there is a single duct leading as far as the stomach; the duct for the residue is not clear to perception. The feet and the thorax are hard, but less so than those of the crabs. They are not attached to the shells like the purpuras and the trumpet-shells, but easily separable. The ones in spiral shells are more elongated than those in nerite shells. But the one in the nerite shells is of another kind, though much the same as the others, but of its divided feet, the right one is small and the left one large, and makes progress more with it. An animal of this sort also occurs in shellfishes, where the attachment is much the same, and in others. This is the one people call a "hermit crab."

The nerite has a shell that is smooth, large, and round; its shape is much the same as that of the trumpet-shells, except that unlike those it has a *mêkôn* that is not black but red. It attaches firmly at the middle.

In good weather these animals detach themselves to feed, but when the wind blows the hermit crabs stay quiet by the rocks, while the nerites attach themselves like limpets. It is the same way with both the hemorrhoids[183] and all of this kind. They attach themselves to the rocks, when they turn back the operculum; for this seems to be a sort of lid; for where the bivalves have a second valve, the spiral-shelled animals have this other part. Their inner part is fleshy, and in it is the mouth. It is the same way in the hemorrhoids, the purpuras, and all animals of this sort.

All those that have the left foot larger [than the right] do not appear in spiral shells, but do appear in nerite shells. There are also some snail shells that have animals in them like the small crayfishes that occur in rivers; they differ from these in that the part they have inside the shell is soft. What the appearance of these is like must be observed with the help of the *Dissections*.

4.5
Urchins

The urchins have no fleshy part, which is a special affection of theirs; for they are all deprived of it, and have no flesh at all inside; but they all have the black entities.[184] There are many kinds of urchins, one of which is for eating; this is the one in which

183. Identity unknown.
184. Also 530^{b}13, 31, *PA* 680^{a}14. Their identity is unclear.

530ᵇ1 the so-called eggs are large and edible, alike in the large ones and in the small ones; for even at the outset, when they are still small, they have these. But there are two other kinds, that of the *spataggês* and that of the so-called *brussos*; both are deep-sea dwellers and rare. Further, there are the so-called mother urchins, which are the largest of all in size. In addition to these there is another kind, small in size, but with large hard spines, which occurs in the sea many fathoms deep, and which some people use to treat stranguries.[185] Around Torone there are white sea urchins whose shells, spines, and eggs are white, and whose length is greater than the others, while the spines are neither large nor strong but softer. The black entities arising from the mouth are more numerous and connect with the duct leading outside,[186] but do not connect with each other; the animal is, as it were, divided by these.

The edible urchins move the most and most often. A sign of this is that they always have something on their spines.[187]

All the urchins have eggs, although in some they are altogether small and inedible. One finds that the urchin's so-called head and mouth are down below, but that the outlet for the emission of residue is up above. The same thing occurs in all the spiral-shelled animals and the limpets; for their food comes from down below, so that the mouth is situated in relation to the food, while [the outlet for] the residue is up above by the back of the shell. The urchin also has five hollow teeth inside and, in the middle of them, a fleshy body in place of a tongue. Next to this is the esophagus, then the stomach, which is divided into five parts and is full of residue; all its folds connect in one at the outlet for the residue, where the shell is perforated. Under the stomach, in another membrane, are the so-called eggs, the same odd number in all of them (for they are five in quantity). Up above, the black entities are attached to the starting-point of the teeth; they are bitter and inedible. In many animals one finds a part of this sort or its analog—for example, the turtle, the toad, the frog, the spiral-shelled animals, and the
531ᵃ1 soft-bodied animals; but it differs in color, and in all animals of this sort is inedible either altogether or more or less so. With respect to its starting-point and end-point the body[188] of the urchin is continuous, although with respect to its surface it is not continuous, but, when it is without its surrounding skin, is like a lantern.[189] The urchin uses its spines as feet; for by leaning on these and moving it changes its place.

185. The eggs of sea urchins were used as diuretics to treat this condition, which is caused by irritation or blockage at the base of the bladder.
186. The outlet for the residue.
187. *PA* 681ᵃ7–9 explains.
188. Reading σῶμα for στόμα ("mouth [apparatus]").
189. I.e., when the spines and skins have been removed its yellow interior looks like a spherical lantern.

4.6
Sea Squirts

Among all these animals, the so-called sea squirts have the most extraordinary nature. For they alone have the body completely hidden inside the shell, and the shell is intermediate between skin and shell, which is why it cuts like hard leather. The animal attaches to the rocks by its shell-like part, and has two ducts at a distance from each other, altogether small, and not easy to see, by which it emits and takes in the water; for it has no visible residue in the way that, among the other shellfishes, some are like the urchin, while others have the so-called *mêkôn*. When opened up, one finds, first, a sinewy membrane around the shell-like part; and inside this is the flesh itself of the sea squirt, which is like that of none of the other hard-shelled animals; this flesh, however, is the same in all of them.[190] It is attached at two places on the side to the membrane and the flesh; and the place where it is attached is narrower on both sides at the places where it extends to the ducts going outside through the shell, where it emits and takes in the nourishment and the water, as if one duct were a mouth and the other an outlet for the residue. One of these ducts is thicker and the other thinner. Inside, there is a cavity on each side, separated by a small continuous entity;[191] in one of these the liquid appears. The animal has no other parts, either instrumental, perceptual, or—as is the case in the other [hard-shelled] animals, as was said previously[192]—for the emission of residues. Some sea squirts are yellow in color; others are red.

The anemone kind is also special; for it is attached to the rocks like some of the hard-shelled animals, though it is sometimes detached. It has no shell; its entire body is fleshy. It has perception: it seizes a hand approaching it and clings to it, just as the octopus does with its tentacles, in such a way that the flesh swells up. It has its mouth in the middle and lives using the rock as a shell. If a little fish strikes against it, it grasps it, just as it did with the hand. And if anything edible comes up against it, it eats it. One kind of the sea nettles[193] detaches itself; it eats urchins and scallops that strike against it. The sea nettle appears to have no residue at all, but to be in this respect like the plants.

There are two kinds of anemones, the smaller and more edible ones and the large hard ones, like the ones that occur around Chalcis. In winter their flesh is firm (which is why they are both hunted and edible), but in summer they are ruined; for they become watery, and if one touches them, they quickly break apart and cannot be detached whole; when they suffer from the heat, they tend to go into the rocks.

The soft-bodied animals, the soft-shelled animals, and the hard-shelled animals, and all their externa and internal parts, have now been spoken about.

4.7
Insects

The insects must now be spoken about in the same way. This kind has many forms included in it; and, though some are kindred, they are not joined together by any common name—as, for example, in the case of the bee, the hornet, the wasp, and all insects of this sort; and, again, all those that have their wings in a wing case—for example, the cockchafer, the stag beetle, the blister beetle, and others of this sort.

There are three parts common to all insects: the head, the trunk containing the stomach, and a third part intermediate between the two, like the chest and the back in the other animals. This is a single part in most of them; but in the long many-footed ones, the intermediate parts are pretty much equal in number to the sections.

All insects when cut in two continue to live, except for the ones that are very cold or that, because of their minuteness, get cold quickly, since even the wasps continue to live when cut in two. When together with the middle part, both the head and the stomach continue to live, but without it the head does not continue to live. All those **532[a]1** that are long and many-footed live for a long time when cut, and the severed part moves toward either of the two extremities, for it moves in the direction of the cut or in that of the tail—for example, the so-called millipede.

All insects have eyes, but no other visible perceptual organ, though some insects have a sort of tongue (as do all the hard-shelled animals), with which they taste and draw in nourishment. This is soft in some of them, in others very strong—as it is in the purpuras. In the horsefly and gadfly too it is strong, as it is in most of the other insects; for in each of them that has no sting in the rear it is like a weapon. All those that do have it, except for a few sorts, do not have teeth; thus, it is by touching [the skin] with it that the flies draw blood and it is with it that the mosquitos prick.

Some insects also have a sting. Some have the sting inside themselves—for example, the bees and the wasps; others have it outside—for example, the scorpion. This is the only insect that has a long sting. It also has claws, as also does the scorpion-like insect found in books.[194]

The flying insects, in addition to the other parts, also have wings. Some have two wings, like the flies; some have four, like the bees. No insect with only two wings has a sting in the rear. Further, among the winged insects, some have their wings in a wing case, like the cockchafer. Some are without a wing case, like the bee. The flight of all of them is without help from the tail, and their wing does not have a quill or a

194. *Chelifer cancroides*. Also 557[b]8–12.

divide. Further, some of them have antennas in front of the eyes—for example, the butterflies and the horned beetles.

Among the jumping insects (*pêdêtika*), some have the back legs larger [than the front legs], others have rudder-like legs (*pêdalia*) that bend backward like the legs of the four-footed animals.[195]

All have the back parts different from the underneath parts, as is also the case with the other animals. The flesh of the body is neither shell-like, nor like that inside the hard-shelled animals, nor flesh-like, but intermediate. That is why they have neither spine nor bone, nor anything like sepium,[196] nor a shell around them; for the body **532^{b}1** itself, because of its hardness, preserves them, and needs no other support in addition. They do have a skin, but it is altogether fine-grained.

These, then, are the external parts of the insects and what they are like.

On the inside, immediately after the mouth, there is an intestine in most of them that is straight and simple up to the outlet [for the residue], though in a few it has a coil. No insect has any viscera or fat, any more than any other bloodless animal does. Some also have a stomach, and from this comes the rest of the intestine, whether simple or spiraling, as in the crickets.

The cicada is the only one among the animals of this sort and among the other animals that does not have a mouth but, like the insects that have a sting in the front, it has a tongue-like part that is large, coalescing, and undivided, with which it nourishes itself on dew alone; its stomach holds no residue. There are many forms of cicadas that differ in largeness and smallness and in that the ones called "chirpers" have a division under the diaphragm,[197] and a visible membrane, while the cicadellas do not have it.

There are some extraordinary animals in the sea, which, because of their rarity, it is not possible to put in a kind. For some experienced fishermen have been known to say that they have seen animals in the sea that are like pieces of wood, black, round, and of uniform thickness; others[198] that are like shields, red in color, with fins packed close together; and others that are like the sex organ of a man in appearance and size, except with two fins in place of the testicles, and that were once caught on the end of a line with many hooks.

———

These, then, are the ways the parts of all the animals are, both the external ones and the internal ones, whether special to each kind or common.

4.8
Perceptual Modalities

The perceptual modalities must now be spoken about; for these are not present in the
30 same way in all the animals; instead, some have all of them, others fewer. They are at a maximum (for no other special one is evident beyond these) five in number: sight, hearing, smell, taste, and touch.

The human being, the live-bearing footed animals, and in addition to these the
533a1 blooded egg-laying ones, all visibly have all of these, except if a kind has been subject to a single deformation—for example, the mole. (For this animal does not have sight;
5 it has no visible eyes, but if the thick skin is removed from the head at the external region of the eyes, one finds eyes inside that have been destroyed, having all the same parts as true eyes; for they have the black part[199] and inside the black part the so-called eye-jelly, and the fatty part[200] surrounding it, but these are all smaller than in
10 visible eyes. But on the outside there is no sign of these because of the thickness of the skin, as if, in the process of coming to be, their nature had been deformed. For from the brain where it attaches to the marrow, there are two ducts, sinewy and strong, extending along the sockets of the eyes, and ending at the upper projecting teeth.)[201]

15 The other animals have perception of colors as well as sounds, and further, of odors and flavors. The fifth perceptual modality, called touch, all the other animals possess too.

In some animals the perceptual organs are very visible; this is especially the case
20 for the eyes. For the place of the eyes is distinctive, and so is that of the ears; for some have ears and some have visible ducts. It is the same way with smell; for some have nostrils, while others have olfactory ducts—for example, the bird kind. It is the same way too with the perceptual organ for taste, the tongue.

25 Among the aquatic animals, the ones called the fishes, though they have the perceptual organ for taste, the tongue, have it in an indistinct way; for it is bony and undetached. In some fishes the palate is fleshy (for example, among river fishes, the carp), so that, to
30 those who do not investigate it in an exact way, they seem to have a tongue there. But
533b1 that the fishes have perception of taste is evident; for many of them enjoy particular flavors and very readily take a bait of bonito or one of the fatty fishes, implying that they enjoy tasting and eating baits of this sort.

Of hearing or of smelling the fishes have no visible organ; for what might seem to be one in the region of the nostrils does not end in the brain; instead, some are blind alleys while others lead to the gills. But that they do hear and smell is evident; for they
5 visibly flee from loud noises, like those made by the oars of triremes, with the result

199. 491b21.
200. The white of the eye.
201. This sentence may be an interpolation of more general application, since the mole does not have such teeth.

that they are easily caught in their lairs; for a noise, even if small outside [the water], appears harsh, large, and oppressive to all those that hear under water.

This is in fact what happens in dolphin hunts; for when the hunters have encircled a gathering of them with their dugout canoes, they make a noise from them in the sea that causes the gathering to flee toward the land and run aground, and then they are captured while bewildered by the noise. And yet the dolphins have no visible organ of hearing at all.

Further, in fish hunts, those involved in the hunt take the utmost care not to make any noise with their oars or nets. But when they have observed a large gathering in a certain place, they drop their nets at the sort of place from which they judge that no sound either from oars or the onward movement of the fishing boat will reach the place where the fishes are; and they give order to all the sailors to keep as silent as possible until the gathering is surrounded.

Sometimes, when they wish the fish to gather together, they do precisely the same thing as in dolphin hunts; for they make noise with stones in order that, fearing it, the fish will run to the same spot, and in this way get enclosed in the nets. And before they have them closed in, as was said, they prevent the making of noise, but when they have them surrounded, they immediately give the order to shout and make noise; for when the fish hear the noise and uproar, they fall into the nets due to fear. Further, when fishermen see a large gathering of fish at a distance, feeding on the surface in calm waters and good weather, and wish to see what size and kind they are, if they sail up noiselessly, they can escape notice and catch them while they are still on the surface; but if someone happens to make a noise beforehand, the fish can be seen fleeing.

Further, in rivers there are certain small fishes that some call *kottoi*. Because they slip under rocks, some people hunt them by striking stones against the rocks; moving out in the wrong direction, they fall into [the nets], implying that they hear and are bewildered by the noise. **534ª1**

That the fishes hear, then, is evident from such things. Indeed, some people say that the fishes are the animals that have the sharpest hearing, on the basis of spending time around the sea and encountering many things of this sort. The fishes that have the sharpest hearing are the mullet, the bass, the saupe fish, the *chromis*, and other fishes of this sort. The others have less sharp hearing, which is why they spend more of their time at the bottom of the sea.

It is likewise with regard to smell. For most fish are unwilling to touch a bait that is not fresh; not all are caught with the same sort of bait, but with special ones; and they distinguish them by smell; for some are enticed by foul-smelling baits, as the saupe fish is by excrement. Further, many fishes spend their time in caves, and when fishermen wish to summon them out in a hunt, they smear the mouth of the cave all over with odorous pickles, and going toward those the fish come out quickly. The eel too is caught in this way; for the fishermen put down a pot for pickles and put in the mouth of the pot what is called a "strainer." And, in general, all fishes go quickly

toward the odor of greasy steam.[202] Indeed, fishermen par-broil[203] the flesh of the cuttlefishes to use as bait on account of its odor; for they come more toward that. And they say that they put broiled octopus into their wicker traps for no other reason than its odor of greasy steam.

Further, fishes that go in shoals with the currents, when water in which fish have been washed is thrown out, or foul bilgewater poured out, flee when they smell the odor of these. Also, they say that fishes quickly smell the odor of their own blood; they make this clear by fleeing to a great distance away whenever fish blood is around. And, in general, if one baits one's wicker trap with putrefying bait, the fish are unwilling to enter or even to go near it, while if one baits it with fresh bait that smells of greasy steam, they arrive immediately even from a great distance and enter the trap.

What has been said is most evident in the case of the dolphins; for these, as was said previously,[204] have no visible organ of hearing, yet are caught because they are bewildered by noise. They have no visible organ of smell either, yet their perception of odor is sharp.

That these animals[205] possess all of the perceptual modalities, then, is evident. The remining kinds of animals have been divided into four kinds, which encompass the majority of the animals: the soft-bodied animals, the soft-shelled animals, the hard-shelled animals, and further, the insects.

Among these, the soft-bodied animals, the soft-shelled animals, and the insects possess all of the perceptual modalities; for they have sight, smell, and taste. Indeed, the insects, both winged and wingless, perceive [odiferous] things that are far off—for example, the bees and the *knipes*[206] perceive honey. They perceive it at a great distance, because they recognize it by its odor. Also, many insects are killed by the smell of sulfur. Further, ants leave their ant nests when they are sprinkled with powdered oregano and sulfur, and most insects flee the fumes of burning hart's horn. But they especially flee fumigations with incense.

Further, the cuttlefishes, the octopuses, and the crayfishes can be caught with baits. The octopuses cling so tightly to the rocks that they cannot be pulled off, and stand firm even when being cut; but if one brings fleabane near them, they let go as soon as they smell it.

It is likewise too as regards taste; for the animals pursue distinct sorts of nourishment, and do not all enjoy the same flavors—for example, the bee does not settle on anything putrefying, but on what is sweet, while the mosquito does not settle on anything sweet but on what is acidic.

202. *Mete*. 387[b]6, 388[a]5.
203. *Mete*. 379[b]14.

206. Small ants at *Sens*. 444[b]12.

As for the perceptual modality of touch, as was said previously,[207] it belongs to all the animals.

The hard-shelled animals have smell and taste, which is evident from their baits—for example, in the case of the purpura; for it is enticed by putrefying baits and goes toward this sort of bait because it has perception of it from a distance. That they also have perception of flavors is evident from the same things; for what an animal goes toward because it discerns its odor, it also enjoys the flavor of. Further, all animals that have a mouth enjoy or are pained by the touch of flavored things.

Where sight and hearing are concerned nothing is certain or very evident to perception. But the razor fishes, if someone makes a noise, seem to burrow in the sand, and to flee downward when they perceive the iron approaching[208] (for a small part of them sticks up, but the other part is, as it were, in its lair); and the scallops, if one offers one's finger, they open and close up as if seeing it. Also, those hunting nerites never go upwind of them when they are luring them toward their bait, and do not emit any sound but remain silent, on the supposition that they can smell and hear. If a sound is emitted, they say, the nerites flee. The weakest organ of smell among the hard-shelled animals that move by walking appears to be that of the urchins; among the immobile ones, that of the sea squirt and the barnacles.

4.9
Voices and Voiced Sounds

As regards the perceptual organs, then, these are the ways they are in all the animals; as regards the voice of animals, it is the following ways.

Voice and sound are distinct, and speech is a third thing. No other part except the larynx can make a voiced sound; that is why all animals that do not have a lung do not emit a voiced sound either.[209] Speech is the articulation of voiced sound by means of the tongue. Vowels are emitted by the voice and the larynx, consonants by the tongue and the lips; from these speech is composed. That is why all those animals that **$535^{b}1$** do not have a tongue, or one that is not detached, do not have speech. But it is possible to emit a sound with other parts too. The insects, for example, have neither voice nor speech, but they emit a sound with their internal breath, not with the external; for none of them breathes. But some of them buzz—for example, the bee and winged insects of this sort; while others are said to sing—for example, the cicadas. All these animals emit sounds with the membrane that is under the diaphragm in whichever of them is divided there—for example, a certain kind of cicada does so by means of a rubbing of the breath. And the flies, the bees, and all the others do so when flying by

207. $533^{a}17–18$.
208. The iron rod is let down into the burrow between the razor fish's valves and is drawn up when they close around its conical tip.
209. *PA* $664^{a}17$.

the lifting and lowering [of their wings]; for the sound is the rubbing of the internal breath. As for the crickets, they make sound by rubbing with their rudder-like legs.[210]

None of the soft-bodied animals makes either a voiced sound or a natural sound, nor does any of the soft-shelled animals. The fishes, though voiceless (for they have no lung, windpipe, or larynx), emit certain sounds and shrill cries, which is what is called their "voice"—for example, the *lura*, the *chromis* (for these fishes emit a sort of grunt), the *capros*[211] in the river Achelous, further, the *chalkis*, and the cuckoo fish; for the *chalkis* emits a sort of piping sound, and the cuckoo fish emits one that is much the same as the sound of the cuckoo, from which it also gets its name. All these animals emit what seems to be a voiced sound, some by the rubbing of their gills (for these places are spiny), others by means of internal parts around the stomach; for each of these has breath inside it, by rubbing and moving which they make the sounds. Some of the selachians seem to emit a shrill cry. But to say that these emit a voiced sound is not correct, though they do emit sounds. In fact, the scallop, when it spatially moves, leans on the water (which is called "flying"), and makes a whizzing sound; and so does the sea swallow; for these fishes fly aloft, without touching the sea; for they have fins that are broad and long. Just as when birds fly the sound made by their wings is not a voiced sound, so the sound made by these fishes is not one either.

The dolphin too emits a squeak and moans when it emerges [from the water] and
536ᵃ1 is in the air, but not in the same way as the cases mentioned; for this animal has a voice; for it has both a lung and a windpipe, but it has neither a detached tongue nor lips, so that it cannot make an articulated voiced sound.

Among the animals that have a tongue and a lung, those that are egg-laying and four-footed emit a voiced sound, but a weak one: in some cases, a piping sound, like the snakes; in others, a thin and weak voiced sound; and in others a small hissing sound, like the turtles. The frog has a special tongue; for the front part is attached as in the fishes (while in the other animals it is detached), but the part near the larynx is detached and folded up, and with this it emits its special voiced sound. It is the male frogs that make the croaking in water, when they call again and again the females for mating; for each of the animals has a special voiced sound for sexual intercourse—for example, goats, pigs, and sheep. The frog makes the croak by putting the lower jaw on a level with the surface of the water and distending the upper one. The jaws seem to become transparent from the distension, and the eyes appear like lamps; for mating occurs mostly at night.

The bird kind emits a voiced sound; and the ones that most have speech are those that have a broad tongue; also, those that have a thin tongue. In some cases, the male and the female emit the same voiced sound; in others, distinct ones. The small birds have many voices and are more talkative than the large ones; and it is especially around mating time that each of the birds is like this. Some emit voiced sounds

210. *PA* 683ᵃ32–36.

211. All three, along with cuckoo fish, are gurnards.

when fighting—for example, the quail; others before the fight, when challenging another—for example, the partridge; or when they have been victorious—for example, the chicken. In some cases, the males sing in the same way as the females—for example, both the male and the female nightingale do, except that the female stops when she is brooding or has chicks; in some cases, it is rather the males that sing—for example, the chickens and the quails—while the females do not sing.

The live-bearing four-footed animals each emit a distinct voiced sound, but none of them has speech, which is special to the human being; for all the ones that have **536^b1** speech also have a voice, but those that have a voice do not all have speech. All those who are deaf from birth are also mute: they emit voiced sounds, but no speech at all. Children, just as they do not have control of the other parts, also do not at first have control of the tongue, which is incomplete and detaches itself later on, so that they mostly speak inarticulately and lisp.

The voices and the sorts of speech differ in accord with the places. Voiced sound is distinguished mostly by high pitch and low pitch, but does not differ in form among animals of the same kind. In the case of articulated voiced sounds, on the other hand, that one might describe as being like speech, they differ both in distinct [kinds of] animals and in animals of the same kind in accord with the place—for example, among the partridges, some cackle, while others emit a shrill cry. And some small birds do not emit the same voiced sound in singing as their parents, if they are reared away from home and have heard other birds singing. A female nightingale has been observed teaching her chick to sing, implying that the speech and the voiced sound are not the same thing by nature, but that the latter admits of being molded. Human beings emit the same voiced sound, but their speech is not the same.

The elephant emits a voiced sound which, when not with its trunk, but with the mouth alone, is wind-like, and of the sort that a human being makes when breathing out and groaning, but when with its trunk, it is like the sound of a harsh trumpet.

4.10
Sleeping and Waking

As regards the sleeping and waking of the animals, all those that are footed and blooded sleep and wake, as is made evident by perception. For all animals that have eyelids go to sleep by closing them. Further, it appears that not only do human beings dream, but also horses, dogs, cows, and further, sheep, goats, and the entire live-bearing four-footed kind; dogs make this clear by barking [while asleep]. In the case of the egg-laying animals, on the other hand, this is not clear, but that they sleep is evident.

It is the same way with the aquatic animals—for example, the fishes, the soft-bodied animals, and the soft-shelled animals (the crayfishes and animals of this sort). All these **537^a1** animals sleep little, but it is evident that they do sleep. A sign of this is obtained not from their eyes (for none of these has eyelids), but from their keeping still.

For the fishes are caught [while asleep], so that, if not [kept awake] because of lice and so-called fleas, they are easily caught by hand. But as things stand, if they linger, these parasites fall upon them at night and eat them, since they are very numerous. They come about in the depths of the sea, and in such large numbers that eat even the bait, provided it is fish, if it lingers on the bottom; indeed, fishermen often draw up a sort of ball of them clinging to the bait.

But a better proof that fishes sleep comes from the following; for often it is possible to fall upon fishes unawares in such a way that one can catch them by hand or by striking them a blow; for during this time they stay very still, and do not move, except for a slight movement of the tail. It is also clear they sleep from their spatial movements if anything moves when they are at rest; for they move as if from sleep. Further, in torchlight fishing, they are caught because they are sleeping. Often too the tuna-watchers cast a net around them because they are sleeping; this is clear from the fact that they stay very still and show their white undersides while being caught. Fishes sleep more soundly at night than during the day, so much so that, when the net is cast, they remain stationary. Mostly they sleep close to the land, or to the sand, or to some stone on the bottom, or after hiding themselves under a rock or sandbank. Flat fishes sleep in the sand; they are recognized by the outline shape the sand takes and are caught by being stuck with tridents. The bass, the gilthead, the mullet, and fishes of this sort are often caught with a trident during the day because they are asleep; otherwise, it seems that none of the fishes of this sort could be caught with a trident. The selachians sometimes sleep so soundly that they can be caught by hand.
537b1 The dolphin, the whale, and all that have a pipe[212] sleep with the pipe above the sea, and through it they breathe while quietly moving their fins; indeed, some people have actually heard a dolphin snoring.

Soft-bodied animals sleep in the same way as the fishes; likewise the soft-shelled animals.

That insects too are among the animals that sleep is evident from the following sorts of signs; for they remain noticeably still and do not move. This is most clear in the case of the bees; for they stay still and stop buzzing at night. But this is also clear especially in the case of the sorts of insects that are close at hand; for not only do they stay still at night because they do not see sharply (for all hard-eyed animals see indistinctly), but also when they are near the light from lamps it is evident that they stay no less still.

Of all the animals, it is the human being that dreams the most. Among the young, and those who are still small children, dreaming does not occur at all, but starts in most cases around the age of four or five years. But cases have been observed of men and women who have never had a dream at all.[213] In people of this sort, however, if

212. I.e., a blowhole.
213. Cf. *Insomn.* 462a31–b11.

they happened to have a dream in older age, after it, a change occurs having to do with the body, in some cases leading to death, in others to a bad state of health.

As regards perception and sleeping and waking, then, these are the ways they are.

4.11
Sex

The male and the female exist in the case of some animals, not in the case of others, but by way of a sort of similarity they are said to bear offspring and be pregnant.[214] In the stationary animals, there is no male and female, nor, in general, in the hard-shelled animals. In the soft-bodied animals and the soft-shelled animals there is a female and a male, and in all the terrestrial animals, both two-footed and four-footed, and in all those that as a result of copulation give birth to a live animal, whether an egg or a larva. In the other kinds of animals, there either simply is a male or female or there simply is not—for example, in all of the four-footed animals there is the male, on the one hand, and the female, on the other, while in the hard-shelled animals there is not; instead, just as in the plants some are fertile and some are infertile, it is the same in these animals. **538^{a}1**

In the insects and the fishes there are some wholly without this difference between the two sexes—for example, the eel[215] has neither a male nor a female and generates nothing from itself; those who say that some eels are at times seen that have hair-like and worm-like things attached speak unreflectively, without additionally observing where they have these. For no animal of this sort is ever live-bearing unless it is previously egg-laying; and none has been seen with an egg. Besides, all the live-bearing animals have their offspring attached in the womb, not in the abdomen; for otherwise it would be concocted like the nourishment. Some say that the difference between the female and the male eel lies in the male having a larger and longer head, and the female a smaller and more snub-nosed one; but the difference they speak of is not that of female and male but that of kind.

There are certain fishes that are called *epitragias*: the carp and the *balagros* are river fishes of this sort. Fishes of this sort have neither egg nor seminal fluid; those among them that are firm and fat, have a small intestine, and are regarded as the best fishes.

Further, just as in the hard-shelled animals and plants there is what bears and what generates, but not what mates, so it is with fishes of the *psêtta*[216] kind and that of the erythrinus and the channa; for all fishes of this sort are seen to have eggs.

214. *GA* $715^{b}16$–21.
215. 6.16.
216. A flat fish, perhaps the turbot. Also $543^{a}2$, $620^{b}30$.

In all the blooded terrestrial animals that are not egg-laying, the males are mostly larger and longer-lived than the females, except for the mule, where the females are longer-lived and larger. But in the egg-laying and larvae-generating animals, as in the fishes and the insects, the female is larger than the male—for example, the snakes, the venom-spiders, the geckos, and the frogs. And in the case of the fishes it is the same way—for example, the small selachian fishes, most of the fishes that live in herds, and all the rock fishes. That the female fishes live
538ᵇ1 longer than the males is clear from the fact that more older females are caught than males.

In all animals the upper and front parts of the males are better, stronger, and better equipped, while in the female it is the ones that may be called the "hind parts" and "under parts." It is the same way in the case of the human being and in that of the other live-bearing terrestrial animals. The female also has less strong sinews and articulations, and is more fine-haired, in those that have hair; in those that do not have hair, its analog is thinner. And the females are more flabby-fleshed than the males and more knock-kneed, their shanks are thinner, and their feet more arched, in those animals that have these parts.

As regards the voice, all the females have weaker and more high-pitched ones, except the cow, in those that have a voice; for the female cows emit a lower-pitched voiced sound than the males.

As for the parts that by nature belong for strength, such as teeth, tusks, horns, spurs, and all parts of this sort, in some kinds of animals the male has them and the female does not have them—for example, the female deer has no horns; and, among some birds that have spurs, the females have no spurs at all; similarly, the female pigs do not have tusks. In some other cases, though these parts belong to both sexes, they are better and more developed in the males—for example, the horns of bulls are stronger than those of the female cows.

BOOK 5

5.1
Generation of Animals

All the parts, then, that all the animals have, both internal and external, and further, the perceptual parts, voice, and sleep, and what the males and females are like—all these were spoken about previously. It remains to discuss their modes of generation,
539ª1 taking first things first.

These modes are many and of great variety, and though in a way they are unalike, in another sort of way they resemble one another. But since the kinds [of animals] were distinguished previously, we must also now try to make this theoretical investigation

in the same way—except that then[217] we made an investigation of the parts of the human being our starting-point, but now we must speak of the human being last of all, because it involves the most study.

We must start first with the hard-shelled animals, and after that speak in order about the soft-shelled animals and the others in the same way: the soft-bodied animals, the insects, and after that the fish kind, both the live-bearing and the egg-laying of these, then the birds. After that, we must speak about the footed animals, both all the egg-laying and all the live-bearing ones. Some of the four-footed animals are live-bearing, but among the two-footed animals, the human being is the only one.

There is a feature common to the animals, just as also to the plants; for while some plants come to be from seed provided by other plants, others come to be spontaneously, from some sort of composition from a seed-like starting-point; and among these, some get their nourishment from earth, while others come to be on other plants, as was said in the theoretical investigation concerning plants.[218] So too among the animals, some come to be from animals of the same kind as themselves in shape, while others do so spontaneously and not from animals of the same kind as themselves; and among these, some come to be from putrefying earth and plants, as many insects do, while others come to be inside animals themselves from the residues in their parts.

Among the ones where generation is from animals of the same kind, in all of those in which there is the female and the male, generation is from copulation. In the fish kind, however, there are some that come to be that are neither male nor female, but are the same in kind as the other fishes, though distinct in species,[219] while others are altogether special cases.[220] And there are some where there are females but not males; from these the equivalent of wind-eggs in the birds come to be. In the case of the birds, all these eggs are infertile (for their nature is capable of generation only up to the egg stage), unless there is some other mode of sexual intercourse with the males.[221] This will be made clear with greater exactness later on.[222] With certain **$539^{b}1$** fishes, however, when they have eggs that come to be spontaneously, it happens that living animals come to be from them, except that some do it by themselves, others not without the male. As for the mode of generation, it will again be made evident in what follows;[223] for it is pretty much the same as in the case of the birds.

All the ones that come to be spontaneously, then, either in animals, in earth, in plants, or in the parts of these, and that have the male and the female, when these copulate, they generate something that is never the same [in kind] as either of the

progenitors, but is incomplete—for example, from the mating of lice come what are called "nits," from flies larvae, and from fleas egg-like larvae; and from these neither the progenitor [kind] nor any other [kind] of animal comes to be, but only the sorts of things mentioned.

First, then, it is necessary to speak about mating, in all animals that mate, then, after that, about the other modes in order, both the particular ones and those that are common.

5.2
The Live-Bearing Four-Footed Animals; the Birds

Mating occurs in those animals in which the male and the female exist, but the ways of mating are neither the same in all cases nor do they occur in a similar way. For among the blooded animals that are live-bearing and terrestrial, all the males have instruments for the act of generation, but they do not all have sex in the same way. The animals that urinate backward have intercourse rump to rump—for example, the lion, the hare, and the lynx, though the female hare often first mounts the male.

In most of the other animals the mode is the same; for the majority of the four-footed animals engage in copulation in the way possible, with the male mounting the female, and in the entire bird kind this is the way—and the only way—it occurs. But there are differences even among the birds; for in some cases the female crouches on the ground for the male to mount—for example, the bustards and the chickens; in others, the females do not crouch down—for example, the cranes; for in these the male mates by leaping upon the female, and the intercourse is quick, as in the case of the sparrows.

Among the four-footed animals, the bears lie prone, engaging in precisely the
540ᵃ1 same mode of mating as the others that do so on their feet, with the underneath parts of the males against the back of the females. Hedgehogs, on the other hand, mate standing upright, with their underneath parts against each other.

Among the large-sized live-bearing animals, the females only rarely submit to the male deer, or the cows to the bulls, because of the tension in the latter's sex organ; it is rather when withdrawing that the females take in the semen. Indeed, in the case of the deer this has been seen to occur, at any rate, among tame ones. The wolf mates and is mated in the same way as the dog. Cats do not have intercourse back to back; instead, the male stands upright and the female puts herself underneath him. For female cats are by nature eager for sexual intercourse, entice the males to acts of mating, and scream during intercourse. Camels mate with the females sitting, the male mates straddling her, not rump to rump, but like the other four-footed animals; and they pass the whole day with one mating and the other being mated. They retire to a deserted place when they engage in mating, and it is not safe for anyone to approach them but their keeper. The camel's sex organ is so sinewy that bow-strings are actually

made from it. Elephants mate in deserted places, mostly near the rivers and where they usually spend their time; the female crouches with her legs apart and the male mounts her and mates. The seal mates like the animals that urinate backward, and keep together for a long time during mating, as the dogs do. The males also have a large sex organ.

5.3
The Egg-Laying Four-Footed Animals

The four-footed egg-laying terrestrial animals engage in the same mode of mating. For some mount like the live-bearing ones—for example, the land turtle and the sea turtle. {. . .}[224] They have a part in which the ducts join together, and with it they have sex during mating—for example, the toads, the frogs, and all of this kind.

5.4
The Footless Animals

The elongated footless animals, like the snakes and the muraena,[225] intertwine with underneath parts next to underneath parts. The snakes intertwine so very tightly, **$540^{b}1$** indeed, that they seem to form the entire body of a single snake with two heads. The mode is also the same in the lizard kind; for they engage in mating by intertwining.

5.5
The Fishes

All the fishes, except for the broad selachians, engage in mating lying side by side with underneath parts next to underneath parts. The broad ones that have a tail, like the ray, the stingray, and fishes of this sort, do so not only side by side, but also by the mounting of the males on the females, underneath parts to back parts, in all those cases in which the tail's great thickness does not impede it. The angel fishes, and those of this sort that have a large tail, mate only by rubbing underneath parts against underneath parts. There are people, though, who say that they have seen some of the selachians have intercourse back to back, like the dogs.

In all the selachian-like fishes the female is larger than the male; and in pretty much all the other fishes too the female is larger than the male. The selachians include

224. There seems to be a lacuna in the text at this point.
225. Reading μύραινα.

the ones mentioned, the ox fish,[226] the *lamia*,[227] the eagle ray, the torpedo fish, the fishing frog, and all of the shark-like fishes. The selachians have all been observed by many people engaged in these modes of mating; for in all the live-bearing animals copulation lasts longer than in the egg-laying ones.

In dolphins and cetaceans the mode is the same; for they mate with the male side by side with the female, and the time involved is neither short nor very long.

In some selachian fishes the male differs from the female in having two appendages near the outlet for the residue, while the females do not have these, as in the shark-like fishes; for what was said applies to all such fishes.

Neither the fishes nor any other of the footless animals have any testicles at all, but male snakes and male fishes have two ducts that become filled with seminal fluid in mating season, and all emit a milk-like liquid. These ducts join together into a single duct, as in the birds; for the birds have their testicles inside, as do all the egg-laying **541^{a}1** footed animals. This duct elongates and extends itself into the receptive part of the female.

In the live-bearing footed animals, the same duct serves for the seed and for the liquid residue on the outside, but inside it is a distinct duct, as was said previously in discussing the difference in the parts.[228] In those that do not have a bladder, the same duct serves also for the dry residue on the outside; but inside they are near each other. These are the same way in the females of these animals as in the males; for they do not have a bladder, except for the turtle, where the female has one duct, and yet it has a bladder. But turtles are egg-laying animals.

The mating of the egg-laying fishes is less open to observation; that is why most people[229] suppose that the females become pregnant after gulping down the seminal fluid of the males. For this is often seen to occur; for in the mating season the females do this as they follow the males, and they strike them under the abdomen with their mouths, making the emission of the fluid faster and more plentiful. At the time of giving birth, on the other hand, it is the males who follow the females, and gulp down the eggs when they emerge. And it is from the ones left over that the fish come to be. (In Phoenicia, in fact, one is used to hunt the other; for the male mullets attract the females which are netted when they gather together, and the females attract the males.) Because this is often seen, it produced the belief that the activity in question is mating. Yet the four-footed animals do something similar; for in mating season both males and females produce secretions and smell at each other's sex organs. When female partridges stand downwind from the males, they become impregnated; they often do so too on hearing the voice of the male, if they happen to be in heat, and when they are being flown over, from the male breathing down on them. Both the

226. The horned ray.
227. A large shark.
228. $497^{a}24$–28.
229. E.g., Herodotus 2.93.

male and the female keep their mouth wide open and stick their tongue out when engaged in mating.[230]

But the true intercourse of the egg-laying fishes is seldom seen because of the rapidity with which they ejaculate after coming side to side, but even in their case mating has been seen to occur in the way described.

5.6
The Soft-Bodied Animals

541^b1 The soft-bodied animals, such as the octopuses, the cuttlefishes, and the calamaries, all have sex in the same way; for they intertwine at the mouth, fitting tentacles to tentacles. The octopus, when it has rested its so-called head on the bottom of the sea and spread out its tentacles, the other fits itself into the spread-out tentacles, and they make their suckers conjoin with each other.

Some people say that the male too has a sort of sex organ in one of his tentacles, the one in which the two largest suckers are, that this part is sinewy and, up to the middle, is entirely attached to the tentacle, and that with it he enters the nostril[231] of the female.

The cuttlefishes and the calamaries swim around intertwined, with their mouths and tentacles fitted to and facing each other, swimming in contrary directions; and they fit the so-called nostril of one to the nostril of the other. The swimming is effected by one swimming backward and the other in the direction of the mouth. The female lays eggs through the so-called pipe,[232] with which some people say they actually mate.

5.7
The Soft-Shelled Animals

The soft-shelled animals—for example, the crayfishes, the lobsters, the carids, and animals of this sort—mate like the animals that urinate backward, when one turns up its tail and the other puts its tail on it. They mate at the start of spring, near the shore (for the mating of all animals of this sort has often been observed), but sometimes it occurs when the figs start to ripen. The lobsters and the carids mate in the same way.

The crabs copulate at their front parts, uniting their layered opercula to each other. First, the smaller crab mounts the larger at the rear; when it has done this, the larger one turns on its side. The female differs in no respect from the male, except that the operculum is larger, stands out more, and is more thickly covered [with hair]; in it she lays eggs and through it the residue comes out. No part of either is inserted into the other.

230. $560^b13–16$.
231. Called a "funnel" at 524^a10, *GA* 720^b32.
232. I.e., the nostril.

5.8
Mating Seasons: The Insects

Insects copulate at the rear, and the smaller one—this is the male—mounts the larger.
542a1 The female inserts her duct from below into the male above, not the male into the female, as in the other animals. And in some cases it is evident that this part is disproportionately large compared to the body as a whole, even when the females are very small, while in others it is less. This is evident if one separates mating flies. They are detached from one another only with difficulty; for the copulation of animals of this sort lasts a long time. This is clear in the insects close at hand—for example, the flies and the blister beetles. They all copulate in this way, the flies, the blister beetles, the *sphondulê*, the venom-spiders, and any others of this sort that mate. The venom-spiders—the ones that weave webs—engage in mating in the following way: when the female at the middle of the web pulls on the suspending strands, the male in turn gives a counterpull; having done this many times, they meet and copulate rump to rump; for because of the roundness of their stomachs this is the mode of copulation that fits them.

———

These are the ways in which the mating of the animals occurs. As for the seasons and ages for the mating, these are determined for each of the animals.

The nature of most of them tends to have them engage in sexual intercourse around the same time, when it is changing from winter to summer. And this is the season of spring, which is when most animals—flying, walking, and swimming—have an impulse to copulate. Some mate and give birth both in fall and winter—for example, some kinds of aquatic animals and of birds. But it is most of all the human being that does so in every season, and also many of the animals that live among human beings (because of shelter and good nourishment) and whose pregnancies are short (like the pig and the dog), and those birds that give birth frequently. Many of the animals also have in view the rearing of their offspring and engage in copulation in the fitting season. In the human beings, the male feels the desire for intercourse more in winter, the female more in summer.

542b1 The bird kind, as was said, most mate and give birth in spring and at the start of summer, except for the halcyon.[233] The halcyon lays eggs around the time of the winter solstice. That is why, when good weather occurs at the solstice, the seven days preceding the solstice and the seven days following the solstice are called "halcyon days," as Simonides says in his poem:

> As when in the winter month Zeus admonishes fourteen days
> And mortals call it the holy season that forgets the winds,
> The season when the dappled halcyon nurtures her offspring.[234]

233. 9.14.
234. Fr. 508 Page.

And these days are calm when it so happens that south winds blow at the solstice, when north ones have occurred at the time of the Pleiades.[235] It is said that the halcyon builds its nest in seven days, and in the remaining seven days lays eggs and raises the chicks. In the places around us there are not always halcyon days at the solstice, but in the Sicilian sea there pretty much always are. The halcyon lays around five eggs.

5.9
Mating Seasons: The Birds, Fishes, and Others

The *aithuia*[236] and the gulls lay their eggs on rocks near the sea, two or three in number; but while the gull lays eggs in summer, the *aithuia* lays them at the start of spring, immediately after the solstice, and it broods just like the other birds. But neither of these two birds hides itself.

The rarest of all birds to see is the halcyon; for it is pretty much seen only at the setting of the Pleiades and the solstice. When ships are lying at anchor, it flies around a ship and then disappears immediately, which is why Stesichorus[237] recalls this mode of behavior of the bird.

The nightingale also lays eggs at the start of summer, and lays five or six eggs. It goes into hiding from fall until spring.

As for the insects, the ones that do not go into hiding (for example, the flies and the ants) mate and give birth in winter too, when the weather is good and the south wind blows.

Most wild beasts, the ones that do not superfetate,[238] give birth once a year—for example, the hare.

In the same way, most of the fishes lay eggs once a year—for example, the shoal **543^{a}1** fishes (the ones called "shoal fishes" are the ones caught in nets), the tuna, the young tuna, the mullet, the *chalkis*, the coly-mackerel, the *chromis*, the *psêtta*,[239] and fishes of this sort, except the bass. It alone lays eggs twice, and the second offspring are weaker [than the first]. The *trichias*[240] and the rock fishes also lay eggs twice a year; the red mullet alone lays eggs three times. This is proved from its seed; for the seed appears three times a year in certain places. The scorpion fish lays eggs twice. The sargus too lays eggs twice a year, in spring and fall. The saupe fish lays eggs once, in fall. The female tuna lays eggs once, but because some fish lay eggs early and others late, it seems to lay eggs twice. The first giving birth is in the month of Poseideon[241] before

235. In early November if the reference is to the morning setting of the Pleiades, as at 542^{b}23.
236. Perhaps the shearwater.

the solstice, the second in spring. The male tuna differs from the female in not having under the abdomen the fin that is called the *aphareus*.[242]

5.10
Mating Seasons: The Fishes (1)

Among the selachians, only the angel fish lays eggs twice; for it lays them once at the start of fall and a second time at the setting of the Pleiades, but is in a more thriving condition in fall. From a single giving birth around seven or eight offspring come to be. Some of the sharks—for example, the starry shark[243]—seem to lay eggs twice a month;[244] this happens because not all eggs reach completion at the same time.

Some fishes lay eggs in any season—for example, the muraena. This fish lays a great many eggs, and from being small the offspring grow rapidly, as with the offspring of *hippouros*[245]—for these too from being very small rapidly become large—except that the muraena lays eggs in all seasons, the *hippouros* in spring. The *smuros* differs from the muraena; for the muraena is variegated and weaker, while the *smuros* is unicolored and strong; its color is like that of the pine tree, and it has teeth outside as well as inside. People say, as in other cases, that one is the male and the other the female. These fishes come out onto dry land and are often caught.

Pretty much all the fishes grow rapidly, and, among the small fishes, not least is
543b1 the crowfish;[246] this fish lays eggs near the shore in thick seaweed. The sea perch too, from being small, quickly becomes large. The young tuna and the tuna lay eggs in the Black Sea, but nowhere else. The mullets, the giltheads, and the bass mostly do so where rivers flow into the sea. The *orkus*, the scorpion fishes, and many other kinds of fishes do so in the deep sea.

5.11
Mating Seasons: The Fishes (2)

Most fishes lay eggs in the three months of Munichion, Thargelion, and Scirrophorion.[247] A few do so in fall—for example, the saupe fish, the sargus, and other fishes of this sort, which lay eggs a little before the fall equinox, as well as the torpedo fish and the angel fish. Some even lay eggs in winter and summer, as was said previously[248]—for

242. No such fin, or other mark of sexual difference, exists.
243. The nursehound, *Squalus stellaris*.

245. Perhaps the dolphin.
246. *Chromis castanea.*
247. Mid-March–mid-June.
248. Perhaps 543a4–11.

example, in winter, the bass, the mullet, and the pipefish; and in summer, in the month of Hecatombaion,[249] around the summer solstice, the female tuna, which lays a sort of bag containing many small eggs. The fishes also that go in shoals with the currents lay eggs in summer.

Among the mullets, the *chellôn* starts to become pregnant in the month of Poseideon,[250] as do the sargus, the so-called *smuxôn*, and the gray mullet; they are pregnant for thirty days. Some of the mullets do not come about from copulation, but grow from mud and sand.

For the most part, then, most of the fishes become pregnant in spring; nonetheless, as was said, some do so in summer, in fall, and in winter; but it does not occur in the same way in all of them, either unconditionally or as regards each kind, as it does with most of those that become pregnant in spring; nor are there as many fetuses in a pregnancy as in the other seasons.

In general, then, it must not escape notice that, just as in the case of the plants and the four-footed animals, the seasons make a lot of difference not only as regards the rest of the good condition of the body, but also as regards the frequency of mating and generation of offspring; so too, in the case of the fishes, places themselves make a lot of difference not only as regards size and their good nourishment, but also as regards giving birth and mating, the same ones giving birth more often in one place and less often in another.

5.12
Mating Seasons: The Soft-Bodied Animals and Hard-Shelled Animals

The soft-bodied animals also lay eggs in spring and, among the marine ones, the first **544^{a}1**
to do so is the cuttlefish. It lays eggs at all times of the day, and its pregnancy is fifteen days. When the female has laid the eggs, the male follows along behind, emits his seminal fluid on them, and they firm up. The cuttlefishes go about in pairs; the male is more variegated than the female and blacker on the back.

The octopus mates in winter and lays eggs in spring, at this time it hides for around two months. It lays an egg that is like a vine-tendril, and similar to the fruit of the white poplar. This animal is prolific; for from what is laid a countless number of offspring comes to be. The male differs from the female in having a more elongated head and what fishermen call a white "sex organ" on one of its tentacles. The female broods having laid them; that is why they become of very poor quality;[251] for they do not feed during this period.

The purpuras too are born around spring, and the trumpet-shells when winter is ending. And, in general, the hard-shelled animals are seen to have their so-called eggs

249. Mid-June–mid-July.
250. Mid-November–mid-December.
251. Either in condition or for eating purposes.

in spring and in fall, except the edible sea urchin, which though it has eggs most of all at these times, nonetheless always has some, especially when there are full moons and warm days, except in the straits of Pyrrha. There they are best in winter; for, though they are small, they are full of eggs.

Snails too are all seen to become pregnant during this season.[252]

5.13
Mating Seasons: The Birds

Among the birds, the wild ones, as was said,[253] mostly mate and lay eggs once a year, though the swallow and the blackbird lay eggs twice. The first offspring of the blackbird, though, are destroyed by the winter (for it is the earliest of all birds to lay eggs), but it rears the second offspring to the end.

Tame birds, or birds that can be tamed, lay eggs frequently—for example, the pigeons do so all summer, and so does the chicken kind; for the male chickens mate and the females mate and lay eggs at all times, except in the days around the winter solstice.

544b1 There are many kinds of pigeon-like birds; for the common pigeon and the rock pigeon are distinct. The rock pigeon is smaller; the common pigeon is more easily tamed; the rock pigeon is black, small, red-footed, and rough-footed, which is why nobody rears it. The largest bird of this sort is the ring dove; second, the wine-colored pigeon, which is a little bigger than the common pigeon; and the smallest of these birds is the turtledove. The pigeons lay eggs and rear offspring in all seasons, if they have a warm place and the provisions they need; otherwise, in summer only. The offspring of spring and fall are best; those of summer and the hot season are worst.

5.14
The Ages of Mating

The animals also differ with respect to the age for mating. First, in most of them the excretion of seed does not start at the same time as the capacity to generate offspring, which comes later; for the first seed of the young in all the animals is infertile, or if it is fertile the offspring are weaker and smaller. This is most clear in the case of the human beings and the live-bearing four-footed animals, and in the case of the birds; for the offspring of the former are smaller, and of the latter the eggs are.

252. Spring and fall.
253. 542b2–4.

The age for animals to mate with each other occurs in most kinds at pretty much the same time, unless it occurs earlier because of some monstrosity-producing affection or damage to the nature.

In the human beings, it is a change in the voice and in the sex organs, not only in size but in form, that appears as a sign of this stage, and similarly in the case of the breasts, and especially by the growth of pubic hair. The human being starts to bear seed around the age of fourteen and becomes capable of generating at around twenty-one. In the other animals the pubic region do not become hairy (for some animals do not have hair at all, others do not have it on their underneath parts, or have less than on their back parts), but that the voice changes in some of them is seen clearly. In others, it is in other parts of the body that signs appear of the start of already having seed and of fertility.

Generally speaking, in most animals the female has the higher-pitched voice, and younger animals than older ones; thus the male deer emit a lower-pitched cry than the female. The males emit voiced sounds when it is mating season, the female when **545^{a}1** they are frightened. The voiced sound of the female is short, that of the male is prolonged. The voiced sound of the dogs becomes lower pitched as they get older. The voices of the horses also differ; for the females from the outset have a thin, small voice, while the male, though it has a small one, yet it is louder and lower-pitched than the female's, at any rate; and it gets louder as time goes on. When they are two years old, and mating starts, the voice of the male is louder and lower-pitched, and that of the female is louder and clearer than before, up until the age of twenty, for the most part. After this time, both the males and the females emit weaker voiced sounds.

For the most part, then, as we said, the voice of the males and that of the females differ in that the males emit a lower-pitched voiced sound than the females, in all those cases where there is prolongation of the voiced sound. But this is not so in all animals, indeed in some it is the contrary—for example, in the cows; for in their case the female emits a deeper voiced sound than the male, and the calves than the adults. That is also why the voices of castrated ones change in the contrary way; for the castrated ones change into the female condition.

The times of mating for the animals with respect to age are as follows. The sheep and the goat mate and conceive at the age of one year, especially the goat, and the males mate at the same age. But the offspring of the males differ in these cases from those of the others; for the males become better in the second year, when they are older. The pig is mated and mates first at eight months; the female gives birth at one year (for this corresponds to the period of pregnancy). The male can generate at eight months, but the offspring are poor until he is a year old. But the ages, as was said, are not the same everywhere; for in some places the pigs are mated and mate at four months, with the result that they can generate and rear [the offspring] at six months; **545^{b}1** in other places, the boars start to mate at ten months, and are good up to three years. The dogs, for the most part, are mated and mate at one year, but sometimes even at eight months; this happens more often in the case of the males than the females.

The female is pregnant for sixty-one, sixty-two, or, at most, sixty-three days; but the offspring are never carried for less than sixty days; but if they are, and are born, they are never reared to the end. After giving birth, the female is ready to be mated again in the sixth month, but not before.

The horse starts mating and being mated—so as to generate offspring—at two years, although the offspring generated at these times are smaller and weaker. For the most part, the horses mate and are mated at three years. This gives them an ever better capacity to generate offspring up to the age of twenty years. The male horse mates up to the age of thirty-three years, the female is mated up to the age of forty years, so that mating occurs pretty much throughout life; for, for the most part, the male lives to around thirty-five, the female to beyond forty, though a case has been observed of a horse that lived to seventy-five.

The ass mates and is mated at thirty months; but, for the most part, they do not generate until they are three or three and a half years old. But, again, a case has been observed of a one-year-old ass conceiving and rearing an offspring. Also a one-year-old cow has been observed to bear and rear an offspring; but it grew [only] to the size that might be expected [for a non-adult] and no further.

These are the ways, then, that the starting-points of generation are for the animals.

As regards human beings, the male can generate offspring up to the age of seventy years at most, a woman up to fifty years. But this is rare; for few people at these ages generate offspring. For the most part, the defining mark for males is sixty-five, and for women forty-five.

The sheep gives birth for up to eight years and, if well treated, up to eleven. It both mates and is mated pretty much throughout life. The goats, when they are fat, are less fertile (hence vines that bear no fruit are called "goatish");[254] but if they are made thin, they are able to generate offspring when they mate. The rams mate with the oldest females first, and do not pursue the young ones. The young ones, as was said previously,[255] give birth to smaller offspring than those of the older ones.

The boar is good to mate up to three years, but the offspring of older ones are worse; for he no longer improves nor does his strength. The boar usually mates when he has eaten his fill and has not just mounted another female; otherwise, the mating is of shorter duration and the offspring are smaller.

The female pig gives birth to the smallest number of offspring when it is her first time giving birth; at her second time giving birth she is in her prime. As she grows older, her giving birth is the same, but she mates for a shorter time. When female pigs reach fifteen years, they no longer generate offspring, but are getting old. If a female pig is well fed, she more quickly has the impulse to mate, whether old or young; but if when pregnant she becomes very fat, she has less milk after giving birth. The offspring, as regards the age of their parents, are best when these are in their

254. *GA* 725ᵇ34–726ᵃ6.
255. Perhaps 545ᵃ24–28.

prime and, as regards the seasons, when generated at the start of winter. The worst are those born in summer; for they are small, thin, and feeble. The male, if well-fed, is capable of mating at any time of day or night; but otherwise he is most so in the early morning. As he grows older, it is progressively less, as was also said previously.[256] Often when the males are impotent, whether because of age or because of weakness, and are unable to mate quickly, the female, because of being tired of standing, will lie down, and they have sex side by side. The female pig is most likely to conceive if she drops her ears when in heat; otherwise, when she is in heat again.

The female dogs mate not throughout life but up to a certain prime point, as, for the most part, mating and conception occur until they are twelve years old. Nonetheless, cases have been observed of females being mated and males begetting up to the age of eighteen or twenty. But age diminishes the capacity, with the result that they can neither generate nor conceive offspring, as is also the case in the other animals.

The female camel urinates backward and is mated in the way stated previously;[257] **$546^{b}1$** the mating season in Arabia is around the month of Maemacterion.[258] She is pregnant for twelve months and she gives birth to one offspring; for she is one-offspring-bearing. The female starts mating at three years and the male at three years. After giving birth, one year elapses before the female is ready to be mated.

The female elephant begins to be mounted, at the youngest, when ten years old, and at the oldest, when fifteen; the male mounts at when five or six years old. The mating season is spring. The male mounts again in three years after mating; but if he has made a female pregnant, he does not have intercourse with that one again.[259] The female is pregnant for two years and gives birth to one offspring; for she is one-offspring-bearing. The fetus is as big as a calf two or three months old.

5.15
The Hard-Shelled Animals

As regards the mating of the animals that mate, then, these are the ways they are. The generation of both the mating and non-mating ones must now be spoken about, and the hard-shelled animals first; for these are (one might almost say) the only kind that is wholly non-mating.

The purpuras gather together in the same place and produce the so-called comb. This is like a honeycomb, except not so neat; instead, it is as if many white chick-pea husks were compacted together. None of these, however, has any open ducts, and the purpuras do not come to be from them; on the contrary, these and all the

256. $546^{a}8–9$.
257. $540^{a}13–18$.
258. Mid-October–mid-November.
259. $630^{b}21–22$.

other hard-shelled animals grow from mud and putrefying material.[260] This comb is a sort of excretion both in these fishes and in the trumpet-shelled ones; for the trumpet-shelled ones also make combs. Though the hard-shelled animals that make combs come to be in the same way as the other hard-shelled animals; nonetheless, more of them come to be when others of the same kind have existed beforehand [in the same place]; for at the start of making the comb they emit a viscous slime that gets composed into the husk-like entities. All these dissolve and emit their contents at the bottom [of the sea]; and in this place the tiny purpuras that were composed at the bottom of the sea come to be. Purpuras are caught with these tiny ones on them, some of which have not yet acquired an exact shape. If they are caught before they "lay eggs," they sometimes lay eggs in the fish-baskets, not in some random place, but when they are in the same place, just as they do in the sea, and because of the narrowness, the comb is like a bunch of grapes.

There are many kinds of purpuras, some are large—for example, those that occur in Sigeum and Lectum; others are small—for example, those that occur in Euripus and around Caria. Those that occur in bays are large and rough; in most of those the bloom[261] is black, though in some it is red and small. Some of the large ones attain weights of one mina. Those that occur on seashores or around headlands are small in size, and their bloom is red. For the most part, those that occur in northern regions are black, those in southern regions red. They are caught in spring, when they are making combs; but they are not caught in the dog days; for then they do not feed, but hide themselves and lurk in lairs. They have the bloom between the *mêkôn* and the neck, and the attachment of these is a firm one. In color it looks like a white membrane. This is what people extract; when squeezed it stains and dyes the hand. A sort of blood vessel extends through it; and this, it seems, is the bloom. The rest is in nature a sort of astringent. When the purpuras have made their combs, then their bloom is worst. The small purpuras people break along with their shells; for it is not easy to extract the bloom; with the larger ones they remove the shell and extract it. That is also why they separate the neck and the *mêkôn*; for the bloom is between these, above the so-called stomach. For purposes of extraction, then, it is necessary for them to be separated. People hasten to break them while they are alive; for if the purpura dies beforehand, it vomits out the bloom; that is why they keep them in fish-baskets until they have gathered enough and have the leisure to do it. The ancient fishermen did not lower fish-baskets under the bait or attach them to it, with the result that while being pulled up the purpura often fell off; but nowadays they do attach a fish-basket, so that if the purpura does fall off it is not lost. It falls off most when it is full;[262] if it is empty, even to pull it off is difficult.

As regards the purpuras, then, these are the special affections.

260. *GA* 762ᵃ8–18.
261. Which yields the purple dye.
262. Of honeycomb.

The trumpet-shells come to be in the same way as the purpuras and in the same season. They both have their opercula in the same place, as do the other spiral-shelled animals, and they all have them from birth. They feed by extending the so-called tongue under the operculum. The purpura has a tongue bigger than a finger, with which it feeds and pierces cockleshells, as well as the shell of its own [kind]. Both the purpura and the trumpet-shell are long-lived; for the purpura lives for around six years, and its growth each year is evident from the intervals in the shell of the spiral. **547^{b}1**

The mussels also make combs.

As for the so-called lagoon oysters, wherever there is slimy mud, it is there that the starting-point of these is first composed. The cockles, the clams, the razor fishes, and the scallops get composed in sandy places. Pinnas grow upright from the bottom of the sea in sandy and muddy places. They have within themselves a pinna-guard, in some cases a small carid, in others a little crab; if they are deprived of it, they quickly die. In general, all the hard-shelled animals come to be in mud and spontaneously, and are of distinct sorts in accord with the difference in the mud: in slimy mud, oysters; in sandy mud, cockles and the others mentioned; around the hollows of rocks, sea squirts, barnacles, and the prevalent ones[263]—for example, the limpets and the nerites. All the animals of this sort have rapid growth, especially the purpuras and the scallops; for they become completely grown in a year.

Growing inside some of the hard-shelled animals are white crabs, altogether tiny in size, and most numerous in the trough-shaped mussels; then in the pinnas there are the so-called pinna-crabs. They also occur in the scallops and the lagoon oysters; they do not admit of any noticeable growth. Fishermen say that these come to be at the same time as the animals they inhabit. The scallops also disappear in the mud for a certain time, like the purpuras.

The shellfishes, then, grow in the way stated. Some of them grow in willow waters, some on the seashores, some in muddy places, some in hard and rough ones, and some in sandy ones. Some change their places, others do not. Among those that do not change them, the pinnas are rooted in place, while the razor fishes and the cockles, without being rooted, remain in place; when pulled up, they are no longer able to live. **548^{a}1**

{The so-called starfish is so warm by nature that when what it grasps is suddenly taken away, it is well boiled. They say too that it is a great pest in the straits of Pyrrha. Its shape is like the stars in drawings.

The so-called lungs[264] come to be spontaneously.

The shell that painters use is exceedingly thicker and the bloom supervenes on the outside of the shell. Animals of this sort mostly occur around Caria.

The hermit crab comes to be at the start from earth and mud, then enters empty shells. As it grows, it enters again into another larger shell—for example, in that of

263. Alternatively, "the ones that keep close to the surface of the water."
264. The Medusa jellyfishes.

the nerite, or that of the winkle, or that of some other animal of this sort, and often it goes into small trumpet shells. When it has entered, it carries the shell around with it and is nourished in it again; and as it grows , it enters again into another larger one.}[265]

5.16
The Sea Nettles and Sponges

The animals that do not have shells come to be in the same way as the hard-shelled animals—for example, the sea nettles and the sponges—in the hollows of rocks. Of sea nettles there are two kinds. Those that live in hollows do not detach themselves from the rocks; those that live on smooth flat rocks detach themselves and go to other places. The limpets also detach themselves and go to other places.

In the holes of sponges pinna-guards come to be. Over the holes there is a sort of spider web, by opening and closing which they catch small fishes, opening it to let them in, and closing it when they are inside.

There are three kinds of sponges, one is open-structured, one dense, and the third, **548b1** which they call "the sponge of Achilles," is the finest, densest, and strongest one; it is put under the lining of helmets and greaves and lessens the sound of a blow. This is the rarest one. Among the dense ones, the very hard and rough ones are called "goats."

Sponges all grow either on a rock or on sandbanks, and they get their nourishment in the mud. A sign of this is that when they are gathered, they are seen to be full of mud, which is precisely what occurs in other things that grow whose nourishment derives from their attachment. The dense ones are weaker than the open-structured ones because their attachment is less extensive.

Sponges also have perception, so people say. A sign of this is that if a sponge perceives that someone is about to tear it off, it contracts itself and is difficult to detach.[266] It does the same thing when there is a lot of wind and surf in order not to fall off. But there are some people who dispute about this, like the ones in Torone.

The sponge nourishes the animals that are in it, worms and other animals of the sort that, when the sponge is detached, are eaten by the small rock fishes along with its leftover roots; but if the sponge is broken off, it grows again from the remaining part and is restored to its former condition.

The open-structured ones are the largest, they mostly occur around Lycia; the dense ones are the softest; for the sponges of Achilles are firmer than these. In general, those that grow in deep calm waters are softest; for wind and storm hardens them, just like other things that grow, and suspends their growth. That is why sponges in the Hellespont are rough and dense and, in general, those that occur beyond or inside

265. This passage is of uncertain authenticity.
266. 487b9–11.

Cape Malea differ in softness and hardness. But they should not have too much heat either; for then they putrefy, like other things that grow. That is why those near headlands are best, if they are in deep water; for then, due to the depth, they are provided with good mixture of protections against both [extreme temperatures].

When they are unwashed and alive, they look black. Their attachment is not at one point nor at all points; for there are empty ducts in between. A sort of membrane is stretched around their underneath parts; and the attachment there is at several points. On the top, the other ducts are closed, except four or five that are evident to perception; that is why some people say that it is through these that the sponge takes in nourishment.

There is another kind of sponge called the "unwashable" because it cannot be washed. It has large ducts, but all the rest is dense; when it is cut open, it is denser and more viscous than the ordinary sponge, and the whole thing is lung-like. It is mostly about this kind that everyone is agreed that it has perception and is long-lived. In the sea, they are distinguished from the ordinary sponges due to the ordinary sponges being white when the mud is in them, while these are always black.

As regards the sponges and the hard-shelled animals, then, this is their mode of generation.

5.17
The Soft-Shelled Animals

Among the soft-shelled animals, the [female] crayfishes, after mating, conceive and retain their eggs for around three months, Scirrophorion, Hecatombaeon, and Metageitnion;[267] after that, they first lay the eggs in the folds under the stomach, and their eggs grow like larvae. It is the same in the case of the soft-bodied animals and the egg-laying fishes; for the eggs of all of them grow.

The egg of the crayfishes is crumbly and is divided into eight parts. For corresponding to each of the flaps on the side there is a cartilaginous entity to which the egg is attached, and the whole thing is like a bunch of grapes; for each of the cartilaginous entities is divided into several parts. These become visible after being separated, though at first sight the thing appears to be a unit. The largest ones are not those near the duct but those in the middle, and the smallest are those at the extremities. The size of the small eggs is that of fig seed. They are not directly contiguous to the duct, but in the middle of the animal; for at both ends, toward the tail and toward the thorax, there are two intervals [without eggs], most clearly presented; for this is the way the flaps also grow. The ones on the side cannot enclose the eggs; but when the end flap is superimposed, it covers all of them, and becomes a sort of lid for these. It seems

267. From mid-May to mid-August.

549ᵇ1 that, when laying its eggs, it brings them toward the cartilaginous entities by folding back the flat of its tail, and at once squeezing the eggs together[268] and staying doubled up, lays them. The cartilaginous entities increase in size in these seasons and become receptive of the eggs; for the animals lay their eggs into these cartilaginous entities, just as the cuttlefishes do into twigs and debris. This is the way, then, in which it lays its eggs, and after concocting them there for around twenty days, it jettisons them in a compact mass, as is evident to perception once they are outside; then from these the crayfishes come in around fifteen days, and they are often caught less than a finger-breadth in size. The crayfish lays its eggs before the rising of Arcturus[269] and jettisons them after it. In the hunchback carids pregnancy is around four months.

The crayfishes live in rough and rocky places, the lobsters in smooth ones; but neither lives in muddy ones; that is why lobsters occur in the Hellespont and around Thasos, and crayfishes around Sigeum and Mount Athos. Fishermen take the bearings of rough and muddy places from the headlands and other signs of this sort, when they wish to fish in the deep sea. In winter and spring, they live more near the shore, in summer, in the deep sea, pursuing in the one case heat, in the other cold.

The so-called bear crabs[270] lay their eggs at much the same times as the crayfishes; that is why in winter and in spring, before they lay them, they are best, and when they have laid them, worst.

The hard-shelled animals cast off their shell in spring, just as the snakes do their so-called old age,[271] both immediately after their birth and later too; both the crabs and the crayfishes do this. All the crayfishes are long-lived.

5.18
The Soft-Bodied Animals

The soft-bodied animals, after copulating and mating, have a white egg; and this in time becomes crumbly, like the eggs of the hard-skinned animals. The octopus lays an egg in lairs, or in a pot or some other hollow thing, that is like vine-tendrils or the fruit of the white poplar, as was said previously.[272] The eggs, when laid, cling around
550ᵃ1 the lair. The number of eggs is so great that when removed they fill a vessel much larger than the animal's head,[273] in which the eggs were contained.

The eggs of the octopus take around fifty days to develop, and from these, when they break, tiny octopuses crawl out, like venom-spiders, in large numbers. The nature of their limbs taken one by one is not yet clearly distinguishable, but their

268. Reading συμπίεσασα.

271. 600ᵇ15–17.
272. 544ᵃ8–9.
273. I.e., its body (523ᵇ24).

shape as a whole is evident. Because of their smallness and weakness the majority of them die. Some have been seen that are so altogether small that they are unarticulated, but that move when touched.

The cuttlefishes lay eggs and these are like large black myrtle-berries; since they are contiguous to each other, the entire thing is like a bunch of grapes, twined around a single one, and not easy to tear apart. For the male emits over them a sort of mucus-like liquid; and this supplies the viscosity. These eggs increase in size; at the outset they are white, but when the male has emitted the seminal liquid, they become larger and black. When the little cuttlefish has developed (it is entirely inside the egg and from the white part that it comes to be), the egg breaks, and it emerges. It comes to be when the female first lays the egg, which is like a sort of hailstone; for it is from this that the small cuttlefish grows, attached at its head, just as the birds are at the stomach. What sort of thing this umbilicus-like attachment is has not yet been observed, except that as the small cuttlefish grows the white part gets progressively smaller and, in the end, like the yolk [of the egg] in birds, the white part in these animals disappears. Just as in the other animals, the parts that first appear largest in these too are the eyes. Let A be the egg, B and C the eyes, and the small cuttlefish itself D.[274]

The cuttlefish conceives in spring and lays its eggs after fifteen days. When they have been laid, after another fifteen days something like a bunch of grapes comes about, and when these break, the small cuttlefishes come out. But if one splits open the egg before that, when they have already reached completion, the small cuttlefishes emit excrement, and their color changes from white to redder because of fear.

The soft-shelled animals incubate their eggs by placing them underneath themselves; but the octopus, the cuttlefish, and the other animals of this sort, when they **$550^{b}1$** have laid them, incubate them wherever their embryos happen to be, especially the cuttlefish; for its cavity is often seen on the eggs and on the earth. The female octopus sits sometimes on her eggs and sometimes at the mouth of her lair, extending her tentacles. The cuttlefish lays its eggs on the earth, around clumps of seaweed, clumps of reeds, and any sort of detritus, such as wood, twigs, or stones. And fishermen put down twigs for this purpose and on these the cuttlefish lays a long continuous string of eggs, like a vine-tendril.

The cuttlefish lays and spurts out its eggs with effort, as if the emission were accompanied by pain. The calamaries lay their eggs in the deep sea; like the cuttlefish, they lay their eggs in a continuous mass. The large calamary and the cuttlefish are short-lived. For, with a few exceptions, they do not live beyond a year. The same goes for the octopuses. From one egg comes one small cuttlefish. It is the same way in the case of the calamaries.

The male calamary differs from the female; for the female, as one could observe on opening its gill region, has two red entities that are like breasts, while the male

274. The reference is to a diagram, but it is unclear what exactly it is intended to illustrate. See *GA* $758^{a}23–25$.

does not have them. The cuttlefish also exhibits this difference, and the male is more variegated than the female, as was said previously.[275]

5.19
The Insects

As regards the insects, that the males are smaller than the females and mount on their backs, and what way they engage in mating, and that they are detached with difficulty, was said previously.[276] When they have mated, in most cases they quickly generate the offspring.

All the ones that mate give birth to larvae, except one kind of butterfly: these give birth to a hard entity, like a safflower seed, with a humor inside it. From the larvae the animal comes to be, but not from a certain part of it, as it is from eggs, but the whole thing grows and, when it becomes articulated, the animal comes to be.

Some insects come to be from animals of the same kind—for example, venom-spiders and spiders from venom-spiders and spiders, and likewise locusts, crickets, and cicadas. Some come to be not from animals but spontaneously: some from the dew falling on leaves, which in spring is in accord with nature, but often in winter too, when the weather is good and the south wind blows for longer periods of time; some in putrefying slimy mud and excrement; some in pieces of wood, some in pieces of growing plants, others in pieces already withered; some in the hair of animals; some in the flesh of animals; some in their residues, and of these, some in those that have been excreted, others in those still inside the animal—for example, so-called worms. Of these there are three kinds: one named the "flat worm," another the round worms, and third the *askaris* worms. From these nothing else comes to be; the flat worm alone is attached to the intestine and lays a sort of melon seed,[277] which doctors recognize as a sign of who has this worm.

Butterflies (*psuchai*), as they are called,[278] come to be from caterpillars, which come to be on green leaves, and especially on those of the radish, which some call "cabbage." At first, they are smaller than a grain of millet, then they are small larvae that grow, then in three days they are small caterpillars; after that, having grown fully, they do not move, change their shape, and are called "chrysalises." They have a hard sheath and move when touched. They are attached by cobweb-like ducts and have neither a mouth nor any other distinguishable part. After not much time has passed the sheath breaks open and the winged animal we call a "butterfly" flies out of them. At first, when they are caterpillars, they take nourishment and emit residue; but when they become chrysalises, they neither take food nor emit residues.

275. 525ᵃ12.
276. 5.8.
277. Actually, a segment of the worm called the "proglottis."
278. *Psuchai* also means "souls."

It is the same way with the other animals that come to be from larvae, both those larvae that come from the copulation of animals and those that do so in the absence of mating. For the larvae of the bees, the hornets, and the wasps, when they are young, take nourishment and contain visible excrement; but when they pass from being larvae to their transitional state, and are then called "nymphs," they neither take nourishment nor contain excrement, but being enclosed, they do not move until they are fully grown; then, after breaking what the cell is sealed with, they emerge.

Both the *hupera* and the *pênia* come to be from certain other caterpillars of the same sort, which undulate in progressing: they advance one part of the body while doubling up the rest and in this way go forward. Each of these gets its own color from that of its caterpillar.

From a certain large larva, which has horns of a sort and is different from the others, first a caterpillar comes to be when the larva changes, then a *bombulis*, then from this a *nekudalos*; and it is in six months that it makes all these changes of shape. It is the cocoons of this animal that certain women undo, unwinding them and then weaving with the threads; the first to weave them is said to have been a woman in Cos—Pamphile, daughter of Plates.

From the larvae in pieces of withered wood, the stag beetles[279] come to be in the same way; first with the larvae being unmoving, then, when the sheath breaks open, the stag beetles emerge. From the stag beetles {. . .}[280] the mole crickets come to be; these too have wings.

From the small flat animals that run upon the surface of rivers the gadflies come to be; that is why gadflies are most numerous near waters where animals of this sort are.

From certain black and hairy caterpillars that are not large, first, glowworms come to be—not the flying ones; these in turn change, and winged animals come to be from them, which are called *bostruchoi*.[281]

Gnats come to be from river worms. The river worms come to be in the mud of wells and wherever water collects that contains an earthen sediment. At first, this mud putrefies and takes on a white color, then becomes black, and finally bloodred; when it has become like this, things grow from it that are like very tiny strands of red seaweed. For a certain time these move around, still attached; then they break apart and are carried around by the water; these are the so-called river worms. After a few days they stand upright on the water, unmoving and hard; then when the sheath has broken open the gnat is incubated above it, until the sun or the wind sets it moving. Immediately thereafter it flies.

For all the other larvae too and all the animals that break out from larvae, the starting-point of their generation is due to the sun or the wind.

279. Reading κάραβοι here and at 551^b19.

280. There is a lacuna in the text at this point.

281. Literally, "curls of hair."

The river worms come to be in larger numbers and more quickly in places that have all sorts of sediment—for example, in kitchens and in plowed fields; for places of this sort putrefy more quickly. In fall too they come about in larger numbers; for then there is less moisture.[282]

The ticks come to be from dogtooth grass, the cockchafers from larvae in the dung of cows and asses. The dung beetles roll excrement into a ball, hide inside it in winter and give birth to small larvae; dung beetles come to be from these. Winged animals also come to be from the larvae in the pulses, in a way similar to the ones mentioned.

The flies come to be from the larvae in manure when a part is separated out;[283] that is why those concerned with working on this separate out the rest of what has been mixed, and say that then the manure has been "worked up." The starting-point of the larvae is small; for, first, they become red even there, and from being immobile take on movement, as if naturally; then a small immobile larva emerges; then, after moving, it becomes unmoving again; and from this comes a completely developed fly, and is set moving by wind or sun. The horseflies come to be from pieces of wood. The bud-eaters[284] from small larvae undergoing change; these larvae come to be in the stalks of
552[b]1 cabbages. Blister beetles come to be from caterpillars that are on fig, pear, or fir trees (for larvae come to be on all these), and also from those on the dog rose; and they are also impelled by foul-smelling things because they came to be from wood of such sort. The mosquitos come from small larvae that come to be from vinegar sediment.

In fact, animals even appear in things that seem to be least subject to putrefaction—for example, in old snow. For old snow becomes redder, which is why the larvae in it are of this color; they are hairy too; but those in Media that come from snow are large and white; all are hard to set moving. In Cyprus, in places where copper ore is smelted, and thrown there for many days, beasts come to be in the fire; they are small but larger than large flies, are winged, and hop and go about through the fire. The larvae and these beasts die when separated from the fire, in the one case, and from the snow, in the other. That it is possible for certain animals to be composed so as not to burn, the salamander makes evident; for it, they say, by walking through the fire puts the fire out.

On the river Hypanis in the Cimmerian Bosporus around the time of the summer solstice, sacs of a sort, larger than grapes, are carried down by the current, from which, when they break open, a winged four-footed animal emerges. It lives and flies until evening, but as the sun goes down it wastes away, and at sunset it dies, having lived one day, that is why it is called the "dayfly."

Most of the animals that come to be from caterpillars and larvae are at first held fast by spiderwebs.

This, then, is the mode in which these animals come to be.

282. *GA* 763[a]29–30.

283. Probably the old manure that has already putrefied, the rest being the newer part of the mixture that has not yet putrefied.

284. Curculionid beetles, probably *Haltica oleracea*.

5.20
The Tracker Wasps

The wasps that are called "trackers," which are smaller than the others, carry venom-spiders they have killed to a wall or some other sort of place that has a hole in it, and, coating[285] it with mud, lay their eggs in it, and from these the tracker wasps come to be. Some of the coleopterans, and some of the small nameless animals, make small mud holes either on tombstones or walls and lay their larvae there. **553^a1**

In pretty much most cases, the time of generation from start to end is three or four weeks. For most larvae and larvae-like animals it is three weeks; for the egg-laying ones, for the most part, four. Among these, seven days after mating, the eggs are composed, and during the remaining three weeks the adults brood and hatch the offspring, as in the case of the spiders and other animals of this sort. For most of them, the changes take place after three or four days, in just the way that crucial moments occur in diseases.

This, then, is the mode of generation of the insects. They die when their parts shrivel, just as the larger animals do in old age. When winged insects die, their wings also contract in fall; as to the horseflies, when they die, their eyes also become dropsical.

5.21
The Bees (1)[286]

About the mode of generation of the bees people do not all accept the same view. For some say that the bees neither give birth nor mate, but fetch the seed: some say, from the flower of the reed; some, from the flower of the *kalamos*; some, from the flower of the olive—and a sign of this, they say, is that when the olive crop occurs, that is when the most swarms are sent forth. Others say that they fetch the seed of drones from some of the plants mentioned, but that the seed of bees is begotten by the leaders.[287]

Of the leaders there are two kinds: the better one is yellowish-red, the other black and variegated; their size is double that of the worker bees; the part below the diaphragm is one-and-a-half times as large as the rest. They are called "mothers" by some people, on the supposition that they do the generating. A sign of this, they say, is that the seed of drones appears even when there is no leader present, while that of the bees does not appear. Others say that they mate, and that the drones are male, the bees female. **553^b1**

285. Reading καταχρίσαντες.
286. Also 9.40, *GA* 3.10.
287. The king (actually queen) bees.

The generation of the bees other than the leaders takes place in the cells of the comb; the leaders come to be below the comb, where they are suspended separately, six or seven of them, and grow in a contrary way to the rest of the seeds.

The bees have a sting, but the drones do not. The kings or leaders have a sting, but do not sting; that is why some people think that they do not have one.

5.22
The Bees (2)

The following are the bee kinds. The best kind is small, round, and variegated; another is large and similar to the hornet; a third is the so-called robber (it is black and has a flat abdomen); a fourth is the drone, in size the largest of all, but stingless and sluggish; that is why some beekeepers put netting around the hives so that the bees can enter, but the drones cannot, because they are too large.

There are two kinds of leaders, as was said previously.[288] There are several leaders in each hive, and not only one; the hive is destroyed if there are not enough leaders present in it (this is not because there is anarchy, but rather, as some people say, because they contribute to the generation of the bees), but also if there are many leaders; for they break it apart.

When spring is late, and when there are droughts and blight,[289] the seed is less; but when there is a drought they work more on the honey, while when there is a lot of rain, more on the seed. That in fact is why olive crops and swarms occur at the same time.[290]

They work first on the comb, then deposit the seed into it, "from their mouth," as some people (those who say that they fetch the seed from elsewhere) say; then in the same way they deposit the honey for nourishment, part in summer and part in fall; fall honey is better. The comb is produced from flowers; the sealant they fetch from the gum of trees; the honey is what falls from the air,[291] especially at the risings of the stars and when a rainbow falls [to earth]; in general, there is no honey before the rising of the Pleiades.[292]

The bee, then, as was said, makes the comb from flowers; but the honey it does not make, but fetches what falls [on plants]: a sign of this is that within one or two
554ᵃ1 days beekeepers find the hives full of honey. Further, flowers appear in fall, but [new] honey does not, when [the old] has been removed. Once the original honey has been removed, and there is no or scant nourishment still in the hive, honey should appear, if indeed the bee makes it from flowers.

288. 553ᵃ25–30.
289. Caused by a lot of rain.
290. 553ᵃ20–23.
291. I.e., dew.
292. Early in May.

Honey becomes composed when it is concocted; for, at the start, it is like water and stays liquid for several days (that is why if it is removed during these days, it does not have thickness), but in around twenty days it becomes composed. The honey from the [flower] juice is immediately clear to perception; for it differs in sweetness and in thickness. The bee fetches it from all the flowers whose flower is in the shape of a calyx, and from all the others that have sweetness, without damaging the fruit; and taking up the juices of these with the part that is tongue-like, they carry them off. The swarms have their honey taken when the wild fig appears. They generate the best grubs when the honey is being worked on. The bee carries the wax and the *erithakê*[293] around its legs; it vomits the honey into the cell. When it has released the larva, it broods like a bird. In the comb, the larva, which is small, lies obliquely; later, it rises up straight on its own and takes nourishment, and is held by the comb so as to be its captive.

The seed of the bees and of the drones is white, and from it the larvae come to be, which, when they grow, become bees and drones. The seed of the kings is reddish in color, and its fine texture is like that of thick honey. Its bulk from the outset is much the same as that of what comes to be from it. A larva does not come to be from it beforehand, but rather a bee appears[294] directly. When a bee has laid [a seed] in the comb, there is always honey right opposite it. The grub grows feet and wings when it is left captive; and when it has reached the end of its development, it breaks open the membrane, and flies out. It emits excrement while still a larva, but not afterward, **$554^{b}1$** except if it does not get out, as was said previously.[295]

If one removes the head of the grub before it has wings, the bees eat these; if one nips off a drone's wings and lets it go, the bees themselves eat off the wings of the remaining drones.

The life of the bees is six years; but some live for seven. If a hive lasts for nine or ten years, it is believed to have survived well.

In Pontus there are some very white bees; these produce honey twice a month. (The bees in Themiscyra, near the river Thermodon, make combs in the earth and in hives that contain not much—indeed, very little—wax, but thick honey; the comb is smooth and even.) They do not do so always, but in winter; for in Pontus there is a lot of ivy, which flowers in that season, from which they fetch the honey. A white and very thick honey is brought down to Amisus from higher up, which the bees produce without combs against trees. Honey of this sort is also produced in other places in Pontus. There are also bees that make triple combs in the earth; these contain honey, but do not contain larvae. Not all combs are of this sort, nor do all bees make this sort.

293. Probably beebread. Also $623^{b}23$ (*kêrinthos*), $626^{a}7$ (*sandarakê*), $627^{a}22$ (*erithakê*).
294. Reading φαίνεται.
295. $551^{a}29$–$^{b}5$.

5.23
The Hornet and the Wasp

The hornets and the wasps make combs for their seed. When they have no leader but are wandering about and not finding one, the hornets make them in some high place, the wasps in holes; when they have a leader, under the earth. All their combs are hexagonal, like those of the bees, but they are not composed of wax; instead, their comb is composed of a bast-like and spiderweb-like material. The comb of the hornets is much neater than that of the wasps. Just like the bees, they deposit a seed, the size of a drop, on the side of the cell, and it adheres to the cell
555ᵃ1 wall. But there is not seed present in all the cells at the same time: in some there are animals already large enough to fly; in some, nymphs; in some, those that are still larvae. There is excrement only around the larvae, as also with the bees. For as long as they are nymphs, they are unmoving, and their cell is sealed up. Right opposite the seed in the cell, there is honey, the size of a drop, in the combs of the hornets. The grubs [of bees and hornets] appear not in spring but in fall; they grow most noticeably at times of the full moon. The seed and the larvae do not adhere to the bottom of the cell, but to the side.

5.24
The Bombukia

Some of the *bombukia*[296] build a pointed nest of clay against a stone or something of that sort, and coat it with some sort of spittle. This nest is very thick and hard; indeed, it is barely possible to break it apart with a spear head. It is there that they lay their eggs and there that small white larvae come to be inside a black membrane. Separate from the membrane, in the clay, there is wax present; this wax is much paler than that of the bees.

5.25
The Ants

Ants also mate and give birth to small larvae that do not attach to anything; these keep growing from small round entities at first until they become larger and articulated. Their generation occurs in spring.

296. Perhaps mason bees, though their nest is rounded.

5.26
The Land Scorpions

Land scorpions also give birth to numerous small egg-like larvae, and they brood. When their development is complete, the parents are thrown out and killed by the offspring, as in the case of the spiders; for often the number of offspring is around eleven.

5.27
The Spiders

The spiders all mate in the way that was stated previously,[297] and generate small larvae first; for these become spiders by changing in their entirety and not in their parts, since they are round at the start. When the spider has given birth to the larvae, it broods, and in three days they become articulated. All spiders give birth in a web, some in a thin small one, others in a thick one, some entirely within a round container, others encompassed by the web only up to a certain point. **555b1**

The spiders do not all come to be at the same time; but they immediately spring up and emit web. The juice in the larvae when squeezed is the same as in the young spiders themselves—thick and white.

The meadow spiders initially give birth to their larvae in a web, of which one half is attached to the spiders themselves, the other half external; and it is in this that, by brooding, they produce the animals. The venom-spiders give birth to their larvae in a thick basket, woven by them, which is where they brood. The smooth spiders give birth to a smaller number, the venom-spiders a larger number; and when they have grown, they encircle the venom-spider, kill their female progenitor, and throw her out, and often the male too, if they get hold of him; for he broods along with the female. Sometimes there are even as many as three hundred offspring around a single venom-spider.

The small spiders become completely grown in around four weeks.

5.28
The Crickets

The crickets mate in the same way as the other insects, with the smaller mounting the larger (for the male is smaller). The females lay eggs in the earth, after having planted firmly there the tube they have at their tail; the males do not have this. They lay them in a compact mass and in the same place, so that it is like a honeycomb. Then, when

297. 542a12–17.

they have laid them, there egg-like larvae come to be that are enveloped by a sort of fine-grained earth as by a membrane; in this[298] they are thoroughly concocted. These embryos are so soft that they compress if one touches them. They are not on the surface but a little under the earth. When they have grown to maturity, they emerge from the earthen sheath as small black crickets; then their skin breaks open and they immediately become larger.

The females lay eggs at the end of summer, and after having laid them, they die; for at the same time as they lay them, larvae[299] appear around their neck. And the males die around the same time. They emerge from the earth in spring.

Crickets do not occur either in hill-country or in poor soil, but only in flat and broken soil; for it is in the cracks that they lay their eggs. The eggs remain in the earth during winter; but once summer comes, crickets develop from the embryos of the previous year.

5.29
The Locusts

The locusts lay eggs in the same way, and when they have laid them, they die. Their eggs are destroyed by fall rains, when these are abundant; when a drought occurs, locusts come to be in greater numbers, because of not being likewise destroyed, since their destruction, at any rate, seems to lack order, and to come about in whatever way it does by luck.

5.30
The Cicadas

There are two kinds of cicadas: the small ones, which are the first to appear and the last to die; and the large ones (the ones that sing), which appear later and die earlier. In the small ones and the large ones alike, there are some that are divided at the diaphragm (the ones that sing), and others that are undivided (the ones that do not sing). People call the large ones that sing "chirpers" and the small ones "cicadellas"; of these, the ones that are divided sing a little.

Cicadas do not occur where there are no trees; that is why in Cyrene they do not occur in the flatland, but do occur in large numbers around the city, especially where there are olive trees; for these do not produce much shade. For in cold places cicadas do not occur, which is why they also do not occur in thickly shaded groves.

298. Reading ἐν ταύτῃ.
299. Of some parasitic insect.

The large ones and the small ones mate in the same way, with their underneath parts being united together. The male emits into the female, as in the other insects. The female has a sex organ that is divided in two (a female is the one into which the male emits).

They lay their eggs in uncultivated lands, boring a hole with the pointed part they have at the rear, just like the locusts; for locusts too lay their eggs in uncultivated lands, which is why they occur in large numbers in Cyrene. The cicadas also lay their **556b1** eggs in the stakes they use to support vines, boring through the stakes, and in the stalks of the squill. These embryos burrow into the earth.

The cicadas come to be in greater numbers when there is an abundance of rain. The larva, having grown in the earth, becomes a mother cicada[300] (indeed, they are best at this point, before they break open their sheath). When the time of the solstice comes, these emerge at night; the sheath immediately breaks apart, and cicadas come to be from the mother cicadas; these become black and hard immediately, and they sing. The ones that do the singing are males in both kinds; the others are females.

At first the males are more pleasant tasting, but after mating, the females; for they contain white eggs.

As they fly up when one scares them away, they emit a liquid like water (which makes farmers say that they are urinating), have residue, and nourish themselves on dew.

If when moving it, one advances one's finger, bending back the tip and then extending it again, the cicadas better stand their ground than when one extends it from the outset, and they will climb up one's finger; for because of seeing indistinctly, they climb it as if it were a moving leaf.

5.31
The Fleas, Lice, and Other Parasites

All the insects that are not carnivorous but live on the juices of living flesh, such as the lice, the fleas, and the bed bugs, generate from their mating what are called "nits," but from these nothing else again comes to be.

Among these, the fleas come to be from the smallest bit of putrefying material (for wherever dry excrement occurs, it is there that they get composed); the bed bugs come to be from the moist secretion of living animals as it becomes composed outside them; the lice come to be from flesh.

Lice come to be when, as they are about to do so, small eruptions of a sort appear that contain no pus; if one pierces these, lice emerge. In some human beings this is a disease that occurs when there is a lot of liquid in the body. Some,

300. A nymph.

557a1 indeed, have been observed to die in this way, like Alcman the poet, they say, and Pherecydes the Syrian. Also, in certain diseases large numbers of lice occur.

There is also a kind of lice that are called "wild," which are harder than the common sort; these are also very hard to remove from the skin. In the case of children, the heads become lice-infested; in the case of men, less so. Women are more infested with lice than men. All those in whom they appear on the head have fewer headaches.

Lice also appear in many other animals. For even the birds have them; and so-called pheasants, unless they take dust baths, die from the lice. Also all the other animals that have feathers with a quill, and those that have hair, have then. Except the ass, which has neither lice nor ticks. The cows have both; the sheep and the goats have ticks, but do not have lice; and the pigs have lice that are large and hard. In dogs the so-called dog-fleas occur. All the lice, in the animals that have them, come to be from the animals themselves. Lice are more numerous in bathing animals that have lice when they change the waters in which they bathe.

In the sea, lice occur on the fishes, but these do not come from the fishes themselves but from mud. Their appearance is similar to that of the many-footed woodlice, except that they have a flat tail. There is only one form of sea lice, and they occur everywhere, particularly on the red mullet. All these insects are many-footed and bloodless. The gadfly of the tunas occurs around the fins; it is like the scorpions, and about the size of a spider. In the sea between Cyrene and Egypt there is a fish that accompanies the dolphin called a "louse"; it becomes the fattest of all due to having the benefit of abundant nourishment from the dolphin's hunting.

5.32
Mites and Other Small Animals

557b1 Other small animals also come to be, as was said previously.[301] Some do so in wool and whatever is made of wool—for example, moths. These grow in greater numbers when the wool is dusty, and occur most if a spider is shut up inside; for it drinks up any liquid there may be in it, and dries it. This larva also occurs inside a sheath. And an animal occurs in wax that has become old, as in wood, and this is believed to be the smallest of all animals; it is called an *akari*, and is white as well as small. Others occur in books: some are like those in clothes, some like scorpions without the tail, and altogether small. In general, they occur in (one might almost say) everything, both in dry things that are becoming wet, and in wet ones that are becoming dry, and in whatever provides a living for these.

There is also a small larva called a "wood-destroyer," than which no other animal is less strange. For its head, which is variegated, projects outside its sheath; it has feet at its extremity, like the other larvae; but the rest of its body is in a spiderweb-like

301. 5.19.

sheath; and around it are dry twigs that seem to have been stuck to it as it walked along. These twigs, though, are a natural part of the sheath; just as the shell is in relation to the snail, so the entire ensemble is in relation to the larva; and the twigs do not drop off, but can only be pulled off, like natural parts; and if one removes its sheath, the animal dies and becomes as useless as the snail when its shell has been removed. As time goes on, this larva too, like the caterpillars, become a chrysalis, and lives without moving; but what winged animal comes from it has not yet been observed.

The fruits of the wild fig contain the so-called *psên*.[302] This occurs first as a larva, then, when its skin bursts open, the *psên* flies out leaving it behind, crawls into the wild figs through their mouths, and causes the figs not to fall off.[303] That is why farmers hang wild figs on domestic fig trees, and plant wild fig trees near domestic ones.[304]

5.33
The Turtle, the Lizard, and the Crocodile

Among the blooded egg-laying four-footed animals, generation occurs in spring, though mating is not in the same season in all cases, but for some it is spring, for some summer, and for others around fall, so that in each case the season to come is advantageous for the generation of their offspring. **558ª1**

The turtle lays eggs that are hard-skinned and two-colored, like those of the birds, and when it has laid them, it buries them and makes the ground trodden hard above them; when it had done this, it regularly broods on them on the surface; the eggs hatch in the following year. The freshwater turtle emerges from the water to lay its eggs, digs a cask-like hole, lays them in it, and abandons them; after allowing less than thirty days to elapse, it digs them up, hatches them quickly, and leads its offspring into the water immediately. The sea turtles also lay eggs in the earth that are like those of the tame birds, bury them, and brood on them at night. They lay a large number of eggs; indeed, they lay up to a hundred eggs.

The lizards and the crocodiles, both the terrestrial and river crocodiles, lay their eggs in the earth. Those of the lizards hatch spontaneously in the earth; for the lizard does not live for more than a year; indeed, the life of the lizard is said to be six months. The river crocodile lays a large number of eggs, in most cases around sixty, that are white in color, and it broods on them for sixty days (for in fact its life also lasts a long time), and from eggs that are very small comes an animal that is very large; for the egg is no larger than a goose's, and the offspring from it is of a corresponding size, yet it grows to a length of even seventeen cubits. Some say that it grows for as long as it lives.

302. The fig wasp.
303. Reading διὰ στομάτων, καὶ ποιεῖ. The mouths are the figs' ostioles.
304. *GA* $715^{b}21$–25.

5.34
The Snakes

Among the snakes, the viper is externally live-bearing, having first been internally egg-laying; its egg, like that of the fishes, is single-colored and soft-skinned. The offspring appears on the upper side of the egg, and is not encompassed by a shell-like husk, just as those of the fishes also are not. It gives birth to the little vipers in a membrane, which break open in three days; but sometimes those inside emerge after eating through it themselves. It gives birth to them one by one in a single day and gives birth to more than twenty.

558[b]1 The other snakes are externally egg-laying, and their eggs are continuous with each other like beads on women's necklaces; when they have laid them in the earth, they brood on them. They hatch too in the following year.

BOOK 6

6.1
The Birds

Of the generation of the snakes and of the insects, then, and further of the egg-laying four-footed animals, this is the mode.

The birds, for their part, all lay eggs, though the season for mating and giving birth are not the same for all of them. For some mate and give birth (one might almost say) all the time—for example, the chicken and the pigeon. The chicken does so the whole year, except during the two months around the winter solstice.[305] Some, even ones that are true to stock,[306] lay a large number of eggs—up to sixty—before brooding; and yet those that are true to stock are less prolific than those that are not true to stock. The Adriatic chickens,[307] though small in size, lay every day; but they are bad-tempered and often kill their offspring. Their colors are variegated.

Some tame chickens lay twice a day, and cases have been observed where, after laying exceedingly many eggs, they have died suddenly.

The chickens lay eggs, as was said,[308] continuously. The pigeon, the wood pigeon, the turtledove, and the wine-colored pigeon lay two eggs, but the pigeons lay even ten times a year.

305. 544[a]31–33.
306. 488[b]18–20, *GA* 749[b]30–34.
307. Perhaps a kind of bantam (also *GA* 749[b]28–30).
308. 558[b]13–14.

The majority of birds lay eggs in the season of spring. Some of these lay many eggs, but lay many eggs in one of two ways: some lay often, like the pigeons; others lay many eggs, like the chickens. All the crook-taloned birds lay few eggs, except the kestrel; among the crook-taloned birds, it lays the most eggs; as many as four have been observed, but it lays even more.

The other birds lay eggs in nests, but the non-flyers—for example, the partridges and quails—never lay in nests, but on the ground, and cover them with twigs. It is likewise with the lark and the *tetrix*. These birds build their nests in places sheltered from the wind. The bird that the Boeotians call the *eirops* is the only one that goes down into holes in the ground and nests.

Thrushes, like swallows, build their nests of clay, in the high branches of trees; they[309] build them next to each other in a continuous string, so that because of its continuity it is like a necklace of nests. The hoopoe is the only one among the birds doing their hatching by themselves[310] that does not build a nest, but goes into tree trunks and lays its eggs in their hollows, without collecting anything.[311] The {. . .}[312] builds in houses or on rocky cliffs. The *tetrix*, which the Athenians call the *ourax*, builds its nest neither on the ground nor in trees, but in low-growing plants.

6.2
The Egg

The egg of all the birds alike is hard-skinned, if it is fertile and not ruined (for some chickens lay soft ones), and two-colored, the white part outside, the yellow part inside.

The eggs of the river birds and marsh birds differ from those of the birds of dry land; for those of the aquatic birds have proportionally much more yellow than white. And the [exterior] colors of the eggs differ in accord with the kinds of birds; for the eggs of some birds are white—for example, the pigeon's and the partridge's; some are yellow—for example, those of the marsh birds; some are speckled—for example, those of the guinea fowls and the pheasants. Those of the kestrel are red, like vermilion.

The egg itself exhibits a difference; for it is pointy at one end and broader at the other; when coming out, the broader leads the way. Long pointy eggs are females; round ones and those rounded at the pointy end are males.

They are hatched by being brooded on by the birds; nonetheless, this can happen spontaneously in the earth, as in Egypt, where they are buried in a dunghill. And in Syracuse, so they say, a man who loved to drink used to puts eggs in the ground

309. Presumably the swallows are meant; thrushes do not build such nests.
310. I.e., that are unlike the cuckoo.
311. Cf. $616^{a}35$–$^{b}1$.
312. The text is uncertain.

under his sleeping mat, and drink continuously until he had hatched them. And cases have been observed of eggs placed in warm vessels getting thoroughly concocted and hatching spontaneously.

The semen of all the birds is white, just like that of the other animals; when she is mated, the female takes it in up near the diaphragm. At first it appears a white small entity, then red and bloodlike, but as it grows, it becomes yellow or golden all over. At the time when it becomes more ready to hatch, it undergoes differentiation, with the yellow inside and the white outside surrounding it. When its development is complete, the egg detaches itself and emerges at the critical point of changing from soft to hard, so that when it emerges it is not yet hard, but when it has emerged, it solidifies immediately and becomes hard, unless it is diseased when it emerges. Cases have occurred where entities resembling the egg at a certain point in its development (for it is uniformly yellow all over, as the yolk is later on) have been seen in a male chicken that is cut open under the diaphragm (precisely where the females have their eggs); in appearance these are entirely yellow, and in size as large as an egg; in account, these are put in the monstrous class.

Those who say that wind-eggs are the remains of eggs that previously came to be from mating, do not speak truly; for it has been adequately observed that unmated young female chickens and geese lay wind-eggs. Wind-eggs are smaller in size, less pleasant in taste, and more liquid than fertile ones, but are more numerous; when they are put under the female bird, their liquid part does not solidify, but rather the yellow and the white remain as they were. Wind-eggs are laid by many birds—for example, the chicken, the partridge, the pigeon, the peahen, the goose, and the Egyptian goose.[313]

The eggs of brooding females are hatched more quickly in summer than in winter;
560ᵃ1 for the female chickens hatch them in eighteen days in the summer, but in winters sometimes in twenty-five days.

Bird also differs from bird in that one is more fond of brooding than another.

If thunder occurs during brooding, the eggs are ruined.

Wind-eggs that are called *kunosoura* and *ouria* by some people are laid more in summer. Wind-eggs are called *zephuria* by some people because it is evident that in spring female birds are receptive of the winds. They lay something of the same sort if they are stroked with the hand in a certain way.

Wind-eggs become fertile, and eggs that are already present from a previous mating change from one kind to another kind, if, before the yellow changes to the white,[314] the female that has the wind-eggs or the fertile ones from another male bird is mated—that is, the wind-eggs become fertile, and the ones previously present correspond in kind with the male bird that mated second. But if the yellow is already changing to the white, there is no change: the wind-eggs do not become fertile, nor

313. Also 593ᵇ22.
314. 559ᵇ9–12.

do the fertile ones change to the kind of the one mating [second]. Also, if mating is interrupted while the existing entities are still small, what was already present does not at all increase in size afterward; but if mating occurs again, the increase in size is rapid.

The yellow and the white of the egg are of a contrary nature, not only in color, but also in capacity; for the yellow solidifies due to the cold, while the white does not solidify, but becomes more liquid; due to fire, on the other hand, the white solidifies, while the yellow does not solidify, but remains soft, unless it is completely burned, and it is by boiling than by roasting that it gets more composed and dry.

The two are separate, divided from each other by a membrane. The "hailstones" at the starting-point of the yellow do not, as some people suppose, contribute anything to generation: there are two, one above and one below. The following also happens where the yellow and the white are concerned: when, after having taken them out of their shell, one pours several of these together into a vessel and boils them gently, not over an intense fire, all the yellow comes together in the middle and the white forms **$560^{b}1$** a circle around it.

Among the chickens, the young females are the first to lay eggs, at the start of spring, and they lay more than the older birds; but the eggs of younger ones are smaller in size.

In general, if the female birds do not brood on eggs, they weaken and fall ill. After mating, the female birds shudder and shake themselves, and often throw straw around (they sometime do this after laying them too); the pigeons drag their rump on the ground, and the geese dive down under the water.

The pregnancies and the conceptions of wind-eggs occur rapidly in the case of most of the birds—for example, in the female partridge, when it is ready for mating; for if she stands downwind from the male, she becomes impregnated and immediately becomes useless for the hunt;[315] for the partridge seems to have a remarkable organ of smell.

The generation of the egg after mating and in turn the generation of the young bird from the concocted egg do not occur in equal periods of time in all cases, but differ in accord with the sizes of the progenitors. After mating, the egg of the chicken gets composed and completed, for the most part, in ten days; that of the pigeon, in slightly less time. The pigeons are able to hold back the egg even when already on the point of laying them; for if it is annoyed by someone, either around nesting or by having a feather pulled out, or if something else hurts or displeases it, it holds it back and does not lay though it was on the point of doing so.

Special to the pigeons as regards mating are the following. They kiss each other when the male is about to mount the female, otherwise he would not mate. An older male does this the first time; subsequently, however, he mates without having kissed; the younger ones always kiss before they mate. This is, then, something special that

315. *GA* $751^{a}13–24$.

they are doing. Further, the females mount each other when no male is available, after having kissed like the males; and though they emit nothing into each other, they lay more eggs than when fertilized ones come to be. From these no young birds come to be but all eggs of this sort are wind-eggs.

6.3
The Egg of the Chicken

Generation from the egg occurs in the birds in the same mode in all of them, though the times of completion differ, as was said previously.[316]

In the case of the female chickens, after three days and nights have passed the first signs are given; in the case of larger birds than these, the time is longer; in the case of smaller ones, it is less long. During this time the yellow has come to be while going up toward the pointy end, which is precisely where the starting-point of the egg is, and where the egg is hatched; and the heart, which is no larger than a pinpoint of blood, appears in the white. This point beats and moves like an animate being; and from it two blood-vessel-like ducts filled with blood and spiraling lead to each of the two surrounding sheaths when the embryo has grown. A membrane containing blood-filled fibers already encompasses the yolk by this time coming from the blood-vessel-like ducts. A little afterward the body too is already distinctly formed, altogether small at first and white. The head is clearly visible, and in it the eyes, particularly swollen up; and this lasts till late in the process; for it is only after a long time that they become small and contract. At first, the lower part of the body appears to be no part at all in comparison to the upper one. Of the two ducts that extend from the heart, one leads to the encompassing chorion, the other to the yellow like an umbilical cord. The starting-point of the chick comes from the white; its nourishment comes through the umbilical cord from the yellow.

From the tenth day on, the whole chick is clearly visible, and all its parts. Its head is still larger than the rest of the body, and the eyes, not yet having sight, than the head. The eyes, if they are extracted around this time, are found to be larger than beans and black; when their skin is removed, there is a liquid inside, white, cold, and very glittery in the sunlight, but nothing solid.

As regards the eyes and the head, then, this is the way things stand.

At this time the viscera, the region of stomach, and the nature of the intestines, are already evident; and the blood vessels, visibly extending from the heart to the umbilical cord, already exist. From the umbilical cord a blood vessel extends to the membrane encompassing the yellow (the yellow at this time is already liquid, and more so than is in accord with nature); the other extends to the membrane encompassing the whole membrane in which the chick is enclosed, the membrane of the

316. 560ᵇ16–19.

yellow, and the liquid between these. {For as the chick grows, part of the yellow goes upward and part downward little by little, and in the middle is the white liquid; the white is below the yellow, as was the case at first. On the tenth day the white is outermost, already small in quantity, viscous, firm, and pale yellow.}[317] For each of these is assigned to its position in the following way. First, and outermost, next to the shell, is the membrane of the egg—not the membrane of the shell, but the one under it. Within this a white liquid is found, then the chick, and around it a membrane keeping it separate, so that the chick is not in the liquid; under the chick is the yellow, into which one of the two blood vessels mentioned leads, while the other leads to the encompassing white. The entire thing is encompassed by a membrane with a serum-like liquid. Then there is another membrane around the fetus itself, as was said,[318] separating it from the liquid. Under this, surrounded by another membrane, is the yellow, into which extends the umbilical cord coming from the heart and the great blood vessel, so that the fetus is not in either of the liquids.

Around the twentieth day, the chick already utters a cry and moves inside, if one disturbs it after taking apart the shell, and it is already feathered when, beyond twenty days, the hatching of the eggs occurs. The chick has its head over its right leg close to the flank, and its wing over its head. And at this time both membranes are visible: the chorion-like membrane that comes after the outermost membrane next to the shell, to which extends (as was said)[319] one of the umbilical cords (and the chick is by this time wholly within it), as well as the other membrane, also chorion-like, the one around the yellow, into which extends (as was said) the other umbilical cord; both (as was said)[320] come from the heart and the great blood vessel. At this time, the umbilical cord that extends to the outer chorion gets detached from the animal and contracts, while the one that goes to the yellow is joined to the chick by its thin intestine, and most of the yellow is already inside the chick, and there is yellow sediment in the stomach. Around this time too, it emits residue toward the outer chorion, and has it in its stomach; the residue to the outer one is white, and there is a white substance inside. In the end, the yellow, which is always becoming smaller as time goes on, gets altogether used up and is enclosed within the chick (so that ten days after hatching, if one cuts the chick open, there will still be a small piece of the yellow left next to the intestine), but it has become detached from the umbilical cord, and there is nothing in between, but it has been entirely used up.

During the time previously mentioned,[321] the chick sleeps, wakes up, opens its eyes on being moved, and utters a cry; and its heart together with the umbilical cord palpates, as in breathing.

This, then, is the mode of generation from the egg in the case of the birds.

317. This sentence is secluded by many editors.
318. 561^{b}18–19.
319. 561^{b}5–10.
320. 561^{b}4–5.
321. 561^{b}27.

Female birds lay some eggs that are infertile, even ones that result from mating, and when they are brooded on no offspring comes to be. This has been observed especially in the pigeons.

Twin eggs have two yolks. In some the yellows are prevented from comingling by a thin partition provided by the white; others do not have this partition, and the yellows touch each other. Some female chickens lay all twin eggs, and in their case the thing with the yolk has been observed to occur; for a hen has hatched eighteen twin eggs, except those that were wind-eggs. The others were fertile (except that one of the twins is bigger than the other), but the final one was a monstrosity.

6.4
The Pigeons

All the pigeon-like birds—for example, the wood pigeon and the turtledove—lay two eggs, for the most part, three at the most. The pigeon, as was said previously,[322] lays eggs in all seasons; the turtledove and the wood pigeon in spring, not more than twice. The female lays the second ones when those that were laid first have been destroyed; for many females destroy their eggs themselves. It lays, as was said, even three eggs at a time; but it never hatches more than two chicks, and sometimes even only one; the remaining egg is always a wind-egg.

Most birds do not generate anything in their first year. But all birds, once they have started to lay eggs, have eggs (one might almost say) to the end of their life, but in some cases they are not easy to see because of their smallness.

The pigeon, for the most part, lays one male and one female egg, and of these, for the most part, it lays the male one first; and when it has laid it, it leaves an interval of one day, then it lays the second. The male takes its turn of brooding on the eggs in the day, the female at night. The egg laid first gets thoroughly concocted and hatched within twenty days. The mother pierces the egg the day before hatching it. Both parents keep the chicks warm for some time in the same way as they did the eggs. The female is more bad-tempered while rearing the offspring than the male, as are the other animals after giving birth. They lay as often as ten times a year, and some have been observed to lay eleven times, and in Egypt up to twelve. The pigeon mates and is mated in its first year; for it even mates and is mated at six months.

Some people say that the female wood pigeon and the female turtledoves are mated and generate even at three months, producing as a sign the great number of these. They are pregnant for fourteen days, and brood for another fourteen days; in another fourteen days the offspring are such good flyers that it is not easy to catch them.

322. 544b7, 558b11–13.

The wood pigeon, so they say, lives for as long as forty years; the partridges over sixteen. The pigeon, after hatching the offspring, lays eggs again after thirty days. **563ª1**

6.5
The Vulture

The vulture builds its nest on inaccessible rocky cliffs; that is why one rarely sees a vulture's nest or offspring. That is also why Herodotus, the father of Bryson the Sophist, says that vultures come from some other land, unknown to us, saying that a sign of this is that no one has ever seen a vulture's nest, and that vultures suddenly appear in large numbers following along with armies. But though it is difficult to see, nonetheless it has been seen. The vulture lays two eggs.

The other carnivorous birds have not been seen to lay more than once a year; the swallow is the only carnivorous bird that nests twice; if one pricks out the eyes of the swallow's offspring when they are still young, the birds will heal and see later on.

6.6
The Eagle

The eagle lays three eggs but hatches two of them, as said in the verses ascribed to Musaeus: "The eagle lays three eggs, hatches two, and cares for one." So this is in fact what happens in most cases; but three chicks have been observed [in a nest]. The mother ejects one of the two chicks as they grow, wearied by feeding them. It is also said that she goes without food at this same time, in order that she not carry off the offspring of wild beasts; thus, her talons get distorted for a few days and her feathers turn white, and as a result mothers become bad-tempered with their offspring at this time. The bearded vulture[323] takes and brings up the chick that has been ejected.

The eagle broods on the eggs for around thirty days. For the other large birds the period of brooding is about the same—for example, the goose and the bustard; for medium-sized ones—for example, the kite and the hawk—it is around twenty days. The kite lays two eggs in most cases, but sometimes it brings up as many as three chicks; the so-called *aigôlios*[324] at times even brings up four. The raven too does not, as some people say, lay only two eggs, but even more; it broods for around twenty days and then ejects the chicks. Other birds do this same thing too; for often those that lay several eggs eject one chick. **563ᵇ1**

Not all the eagle kinds[325] are the same way as regards the offspring. The white-tailed eagle is bad-tempered, but the black eagles are kind to their offspring as regards

323. $619^{b}34–620^{a}12$.
324. Probably a sort of owl ($592^{b}11$, $616^{b}25$).
325. 9.32.

nourishment, though (one might almost say) all the crook-taloned birds, as soon as their offspring are able to fly, expel them from the nest by striking them blows. And of the other birds, as was said,[326] pretty much the majority do this, and, having nourished their offspring, take no further care whatever of them afterward, except the crow; this bird takes care of them for some time; for even after they can fly, she feeds them while flying alongside them.

6.7
The Cuckoo and the Hawk

The cuckoo[327] is said to come from a hawk undergoing a change, because the hawk, which it resembles, disappears around this time; and indeed it is pretty much impossible to see the other hawks as soon as the cuckoo calls, except for a few days. The cuckoo appears for a short time in summer and disappears in winter. But the hawk is crook-taloned, while the cuckoo is not crook-taloned; further, around the head, it does not resemble the hawk either. In both these respects it is more like the pigeon. It is only in color that it resembles the hawk, except that the variegations of the hawk are like lines, those of the cuckoo like points. However, it size and its flight are much the same as those of the smallest of the hawks, and this bird does disappear, for the most part, at the time that the cuckoo appears, although both have been seen together. Also, a cuckoo has been seen being eaten by a hawk; and yet none of the birds of the same kind does this.

They say too that no one has ever seen cuckoo chicks. The cuckoo lays eggs, but does not build a nest. Sometimes it lays them in the nest of the smaller birds, after eating their eggs, especially in the nests of the wood pigeons, after eating their eggs too. It seldom lays two, most often one. It also lays eggs in the nest of the *hupolais*, which hatches and rears the chicks. It is most of all in this season that the cuckoo becomes fat and sweet-fleshed. The chicks of hawks also become very sweet-fleshed and fat. One kind of them builds nests far off and in precipitous rocks.

6.8
Brooding

With most birds, as was said about the pigeons,[328] the male and the female are brooding on the eggs alternately, but in some cases only for the time when the female leaves the nest to get nourishment for itself. Among the geese, only the females brood on the eggs, and they remain sitting on them throughout the entire thing, once they have started doing this.

326. 563ᵇ3–4.
327. 9.29.
328. 562ᵇ17–18.

The nests of all marsh birds are built in marshy and grassy places; which is why, while sitting quietly on the eggs, the birds can get some nourishment for themselves and not go entirely without food.

Among the crows too the females alone brood on the eggs and remain on them throughout the entire thing; the male nourish the females, bringing the nourishment to them and feeding them. Among the wood pigeons, the female starts in the afternoon and broods the whole night until breakfast time; the male does so the rest of the time.

The partridges make two compartments [in their nests] for their eggs, and the female broods on one lot and the male on the other; and, after hatching, each brings up its own. But the male, when he first brings out the chicks, mates with these.

6.9
The Peafowl

The peacock lives for around twenty-five years, and generates at around three years, in which time its feathers also take on their variegation. Hatching occurs in thirty days or slightly more. It lays eggs only once a year; it lays twelve eggs or slightly fewer; it lays them at intervals of two or three days, not continuously; females laying eggs for the first time lay around eight eggs. The peahen also lays wind-eggs. They are mated in spring and give birth immediately after mating. It molts at the same time as the first trees shed their leaves and starts to regain them again at the same time as these **564b1** begin sprouting. Breeders put the eggs of these birds under a female chicken to brood on, because the male, in flying onto the female when she is doing so, crushes them; it is due to this cause too that the females of some wild birds escape from the males to lay and hatch their eggs. At most two eggs are put under the female chicken; for she is able in brooding to hatch only this many. They take care that she does not get down off the eggs and interrupt the brooding, by providing her with nourishment.

The male birds, at mating time, have noticeably larger testicles,[329] and the ones that mate frequently more noticeable so (for example, the male chickens and partridges), in those that do no mate continuously, less.

6.10
The Fishes and the Selachians (1)

As regards the birds, then, this is the mode of pregnancy and generation. As for the fishes, that they are not all egg-laying was said previously.[330] For the selachians are live-bearing, while the kind consisting of the other fishes is egg-laying. The selachians

329. Reading ἐπιδήλως.
330. 489b1–6, 511a3–5.

are live-bearing, but are internally egg-laying beforehand, and nourish the offspring internally, except for the fishing frog.

The fishes also have, as was said above,[331] different uteruses; for the egg-laying fishes have a uterus that is divided in two and low down; the selachians have one like that of the birds. But it differs from the uterus of the birds in that in some cases the eggs are not composed near the diaphragm, but in the middle[332] along the spinal column; as they grow they change place from there.

The egg of all the fishes is not two-colored but single-colored, and are more white than yellow, both beforehand and also when the offspring is inside. The generation from the egg of the fishes and that from the egg of the birds differ, in that the former does not have the one of the two umbilical cords that extends to the membrane under the shell. Of the two ducts, it does not have the one that, in the birds, extends to the yellow. The rest of the generation from the egg is then entirely the same in the case of the birds and of the fishes; for it occurs at the extremity of the egg, and the blood vessels extend from the heart in the same way at first, and the head, the eyes, and the upper parts are the largest at first. In both cases it is the same way: as the fetus grows
565ᵃ1 the egg always becomes smaller, and in the end disappears and goes inside it, just as in the birds the so-called chick[333] does.

The umbilical cord is attached, a little below the mouth, to the abdomen.[334] When the fetuses are young, the umbilical cord is long, but as they grow it shortens, and in the end is small, until it goes inside, as was said in the case of the birds.[335] The fetus and the egg are encompassed by a common membrane; beneath this there is another membrane, which encompasses the embryo and is special to it; between the two membranes there is a liquid. And nourishment is present in the stomach of the small fishes, just as in those of the chicks, one part of it white, the other yellow.

As for the shape the uterus has, one must observe it in the *Dissections*. It differs from one fish to another—for example, in the shark-like fishes, among themselves and in relation to the broad ones. For in some the eggs attach in the middle of the uterus around the spinal column, as was said[336]—for example, the puppies;[337] and as they grow they move around. Since the uterus is divided in two, and is attached to the diaphragm, as in other animals of this sort, the eggs move around into one or other of the two parts. The uterus—both in this fish and in the other shark-like fishes—has, a little further on from the diaphragm, entities like white breasts, which do not appear if no embryos are present in it.

331. 511ᵃ5–8.
332. 565ᵃ15.
333. The yolk (562ᵃ12).
334. Reading τῇ γαστρί.
335. 562ᵃ5–17.
336. 564ᵇ22.
337. 565ᵇ26.

The puppies and the rays have shell-like entities, in which an egg-like liquid appears. The shape of this shell is like the reeds in a pipe, and there are hair-like ducts attached to the shells. In the case of the puppies, which some call the "spotted" sharks, the offspring come to be when the shell breaks open and falls; in the case of the rays, when they have laid eggs, the offspring comes to be after the shell breaks open. The spiny shark has the eggs up against the diaphragm, above the breasts; when the egg descends, as soon as it gets detached, the offspring comes to be. Generation also occurs in the same way in the case of the fox sharks.[338] **$565^{b}1$**

The so-called smooth sharks have their eggs in the middle of the uteruses in the same way as the puppies and, moving around into each of the two parts of the uterus, they descend. The animals come to be with the umbilical cord attached to the uterus, so that as the eggs get used up the condition of the fetus seems like that of the four-footed animals. The umbilical cord, which is long, is attached to the uterus at its lower part (each one being, as it were, fastened to a cotyledon) and to the fetus in the middle, where the liver is situated. The nourishment present when the fetus is cut open, even if it no longer contains the egg, is egg-like. A chorion and the membranes special to it occur in each fetus, just as in the four-footed animals. The fetuses, when young, have their head upward, but as they mature and reach completion, downward. On the left side, males come to be; on the right, females; and on the same side, males and females together. The fetuses, when cut open, are the same way as in the case of the four-footed animals: all the viscera they have are large—for example, the liver—and full of blood.

All the selachians at the same time have many eggs in the upper part near the diaphragm (some larger, some smaller) and fetuses already lower down; that is why many people think that these sorts of fishes lay eggs and mate each month, because the offspring are not all released at the same time, but often over a long period. But those that are down below in the uterus are concocted and brought to completion at the same time.

The other sharks can release and take into themselves their offspring, also the angelfishes and the torpedo fishes (a large torpedo fish has been observed with around eighty fetuses inside it), while the spiny shark, alone among the sharks, does not take them in, due to its spine.

Among the broad selachians, the stingray and the ray do not take them in, due to the roughness of their tail. The fishing frog also does not take them, due to the size of its head and its spines; indeed, it is also the only one of these fishes that is not live-bearing, as was said previously.[339]

This, then, is the mode of difference between these fishes themselves and of their generation from their eggs. **$566^{a}1$**

338. Also $566^{a}31$.
339. $564^{b}16$–18.

6.11
The Selachians (2)

The males, around the time of mating, have their ducts so full of seminal fluid that, when they are squeezed, the seed flows out white. The ducts, which have two parts, have their starting-point at the diaphragm and the great blood vessel. Around this time the ducts of the males are already distinguishable from the uterus of the females; when it is not this season, they are less distinguishable to one not accustomed to them; for in certain cases and at certain times these are altogether invisible, as was said concerning the testicles of the birds.[340]

The spermatic ducts and the uteruses also have other differences from each other: the former are attached to the loin, while the ducts of the females are easily moved and fasted only by a thin membrane. The way the ducts of the males are must be also observed with the help of the diagrams in the *Dissections*.

The selachians are subject to superfetation, and the female is pregnant for six months at the most. The ones that give birth most often are the so-called starry sharks; for it gives birth twice a month. They start to mate in the month of Maemacterion.[341] The other sharks give birth twice a year, except the puppy: this one does so once a year. Some of them give birth in spring; the angelfish also does so a second time in fall near the winter setting of the Pleiades; the first one is in spring; the second set of offspring thrives much more than the first. The torpedo fish gives birth in the late fall.

The selachians give birth near the shore after coming in from the high sea and the depths, for the sake of the warmth and because of fearing for their offspring.

Among the other fishes none is ever seen copulating outside its own kind, only the angelfish (*rhinê*) and the ray (*batos*) seem to do this; for there is a fish called a *rhinobatos*;[342] for it has the head and front parts of the ray, and the back parts of the angelfish, as if coming from both of these.

The sharks and the shark-like fishes (for example, the fox shark and the dogfish) and the broad fishes (for example, the torpedo fish, the ray, the smooth ray, and the sting-
566[b]1 ray) give birth in the mode mentioned:[343] they are live-bearing after being egg-laying.

6.12
The Cetaceans and the Seal

The dolphin, the whale, and the other cetaceans—whichever ones have no gills but rather [blowhole] pipes—are live-bearing; further, the sawfish and the ox fish; for it is evident that none of these has eggs, but from the outset have an embryo, from

340. 509[b]29–32.
341. Mid-October–mid-November.
342. The common guitarfish.
343. 564[b]16–18.

which, once articulated, the animal comes to be, just as in the human being and the live-bearing four-footed animals.

The dolphin more often gives birth to one offspring, but sometimes two; the whale to two at most and more frequently, or else to one. The porpoise does so like the dolphin; for, in fact, it is like a small dolphin; it occurs in the Black Sea. But the porpoise differs from the dolphin; for it is smaller in size and broader across the back; it has a dark blue color. Many people say that the porpoise is one kind of the dolphins.

All animals that have a pipe[344] exhale and take in air; for they have a lung. And a dolphin, at any rate, has been observed, when it was sleeping, with its snout above water, snoring in its sleep.

The dolphin and the porpoise have milk and suckle; and they take their offspring inside them when they are small. The offspring of the dolphins grow rapidly; for in ten years they reach their final size. The mother is pregnant for ten months. The dolphin gives birth in summer, and in no other season whatever. As it happens, it even disappears at the time of the Dog Star for around thirty days. Its offspring follow along with it for a long time; in fact, the animal is child-loving. It lives for many years; for some have been clearly seen to have lived for over twenty-five years, others for thirty; for fishermen cut the tails of some of them and then let them go, so that in this way they know their ages.

The seal is one of the animals that play a double game; for it does not take in water, but breathes, sleeps, and gives birth on land (but near to the shore), as if it were a terrestrial animal. It spends most of its time, however, and gets its nourishment from the sea; that is why it must be spoken about with the aquatic animals. It is internally live-bearing from the outset, gives birth to live offspring, and ejects a chorion and the rest like a sheep. It gives birth to one, two, or at most three **567^{a}1** offspring. It has two breasts and suckles its offspring like the four-footed animals. It gives birth, like the human being, in all seasons of the year, but especially when the first goats are born. When its offspring are around twelve days old, it leads them into the sea many times each day, accustoming them to it little by little. They go down steep places, but they do not walk, because they are not able to lean on their feet. The seal can draw itself together and contract itself; for it is fleshy and soft and has cartilaginous bones. It is difficult to kill a seal by force, unless one strikes it on the temple; for its body is fleshy. It emits a voiced sound like that of a cow. The female has a sex organ that is like that of a sheep,[345] but all the rest is like a woman's.

As regards the aquatic animals that are either internally or externally live-bearing, then, this is the mode of generation and giving birth.

344. I.e., a blowhole.

345. The mss. βατίδι ("like that of a ray") is probably corrupt.

6.13
The Egg-Laying Fishes

The egg-laying fishes have a uterus that is divided in two and low down, as was said previously[346] (the soft-scaled fishes are all egg-laying—for example, the bass, the mullet, the gray mullet, and the *etelis*, and all the so-called whitefishes, and the smooth ones except the eel), and the egg they have is crumbly. Its appearing so is due to the fact that the entire uterus is so full of eggs that in the small fishes there seem to be only two eggs;[347] for because of its smallness and thinness the uterus is invisible in these fishes.

The mating of all the fishes was spoken about previously.[348]

In most of the fishes there are males and females; but about the erythrinus and the channa there is a puzzle; for all of those when caught contain embryos.[349]

In the fishes that copulate eggs are composed when mating, but they have them without mating too. Some of the river fishes show this clearly; for immediately after being born (one might almost say) and while still small, the minnows contain embryos.

These fishes shed their eggs and, as is said, the males gulp down most of them, while others are destroyed in the water; but those that they lay in the places where they should lay them are saved; for if all of them were saved, the kind of each of them would be altogether vast in number. Also, many of these eggs are not fertile, but only those that the male sprinkles with his seminal fluid; for when the eggs have been laid, the male follows and sprinkles his seminal fluid on the eggs, and from all those sprinkled small fishes come to be, and from the others as luck would have it.[350]

The same thing occurs in the case of the soft-bodied animals. For the male of the cuttlefishes, when the female has laid the eggs, sprinkles them; and it is reasonable to suppose that this same thing is precisely what happens in the case of the other soft-bodied animals as well, but it has been observed only in the case of the cuttlefishes up to the present.

The fishes lay their eggs near the land. The gobies do so near stones; what they lay, however, is flat and crumbly. The other fishes do likewise; for the places near the land are warm and contain more nourishment, and there the embryos are not eaten up by the larger fishes. That is also why in the Black Sea, it is near the mouth of the river Thermodon that most fishes lay their eggs; for this place is without wind, warm, and has fresh water.

346. 564b19–20.
347. 510b24–27.
348. 540b6–15.
349. 538a18–21.
350. I.e., they might not be directly sprinkled on and yet get fertilized.

The other egg-laying fishes lay once a year, with the single exception of the small *phukis*.[351] The male *phukis* differs from the female in being blacker and having larger scales.

The other fishes lay when in seed[352] and emit the eggs; but the fish that some people call the "pipefish," when the time to lay eggs comes, bursts open, and in that way the eggs emerge. For this fish has a sort of partition under the abdomen and the lower abdomen, just like the blind snakes; when it has laid its eggs, the sides grow back together again.

Generation from the egg occurs in the same way in the internally and externally egg-laying fishes; for the embryo comes to be at the extremity of the egg and is encompassed by a membrane, and first to be distinguished are the eyes, large and spherical. This shows clearly that it is not the case, as some people say, that fish embryos develop in the same way as those that come about from larvae; for in the case of those it occurs in the contrary way: the lower parts are larger at first, and the eyes and the head develop later. When the egg has been used up, they become tadpole-like, and at first, though taking no nourishment whatever, they grow from the liquid appearing in the egg; later on, they are nourished by the river water until they are grown. **568ª1**

When the Black Sea is being purged, something they call *phukos* is carried into the Hellespont; it is yellow. Some say that this is the bloom of the *phukos*, from which *phukion*[353] comes. It occurs at the start of summer. By this the oysters and the small fishes in these places are nourished. Some of the seamen even say that the purpura gets its bloom from this.[354]

6.14
The Freshwater Fishes

Marsh fishes and river fishes have embryos at the age of five months, for the most part, and all of them lay their eggs at the end of their first year. Like the sea fishes, these never emit all at the same time, neither the females the egg nor the males the seminal fluid, but the former more or less always have eggs and the latter seminal fluid. They lay eggs in the normal season: the carp five or six times (for it mostly lays its offspring at "the stars"[355]); the *chalkis*[356] lays eggs three times; all the others once a

351. Perhaps the black goby.

353. A sort of rouge.
354. $547^{a}4$–$^{b}1$.
355. The phrase "at the stars (*epi tois astrois*)" occurs again at $600^{a}3$. The reference is probably to the risings of the Pleiades, Arcturus, and the Dog Star.
356. Perhaps the shad. There is also a saltwater fish with the same name ($535^{b}18$).

year. They all[357] lay in the stagnant pools left by overflowing rivers and near the reedy parts of marshes—for example, the minnow and the perch.

The sheatfish and the perch emit a continuous embryo, like the frogs; the coiled up embryo is so continuous that—at any rate, in the case of the perch—fishermen in the marshes can unwind it from the reeds because of its breadth. The larger sheatfish lay their eggs in deep waters, some in water a fathom deep; the smaller ones in shallower waters, mostly near the roots of the willow or some other tree, and also near reeds or near moss. Sometimes these fishes intertwine with each other, a very large one with a small one, and bringing the ducts next to each other, which some call "umbilical cords," through which the seed is emitted, one lets out the egg, the other
568ᵇ1 the seminal fluid. All the eggs that get mixed with seminal fluid appear whiter and larger from the outset—in a day, so to speak. A short time later the fish's eyes become clearly visible; for in all the fishes, just as in all the other animals too, they are what is most noticeable from the outset and appear largest. All the eggs that the seminal fluid does not touch, just as in the case of the sea fishes too, are useless and infertile. From the fertile eggs, as the small fishes grow, a sort of sheath detaches itself; this is a membrane that encompasses the egg and the small fish. When the seminal fluid mixes with the egg, the composition that results from these becomes very sticky and sticks to the roots or wherever the fishes have laid. Where they have laid the most, the male keeps egg-guard, while the female, having laid, goes away.

Growth from the egg is slowest in the case of the sheatfish,[358] which is why the male keeps watch for forty or fifty days, in order that the embryo not be eaten by the little fishes that happen to pass by. Second in slowness is the generation of the carp; nonetheless, when the embryo even of these is saved, it escapes quickly. In the case of some of the smaller [kinds of] fishes, even in three days, they are already small fishes. The eggs grow when touched by the seminal fluid, both on the same day and yet later. The egg of the sheatfish is as large as a seed of bitter vetch; that of the carps and fishes of this sort is as large as a millet seed.

This, then, is the modes in which these fishes lay eggs and generate offspring. The *chalkis*, however, lays eggs in deep waters, crowded together and living in herds. The fish they call the *tilôn* lays them near beaches in spots sheltered from wind; this one is also a fish that lives in herds. The carp, the *beleros*,[359] and (one might almost say) all the other fishes crowd into shallow waters in order to give birth, with one female often followed by thirteen or fourteen males. When the female emits the egg and goes away, the ones following after her sprinkle it with their seminal fluid. Most of the eggs are destroyed; for because the female lays it and goes away, the eggs—those
569ª1 that are not carried off by the current and do not strike against something solid—get scattered; for, apart from the sheatfish, none of the other fishes guards its eggs, except,

357. Cf. 568ᵇ24.
358. 621ª21–ᵇ2.
359. Probably a sort of carp.

if it happens upon a mass of its own seed, the carp. People say, though, that it guards its eggs.

All the male fishes have seminal fluid, except the eel; it has neither egg nor seminal fluid.[360] The mullets go up from the sea to marshes and rivers; eels, on the contrary, go from these into the sea.

6.15
Spontaneous Generation among the Fishes

The great majority of the fishes, as was said,[361] come to be from eggs. Nonetheless, there are some that come to be from mud and from sand, even of those kinds that come to be from copulation and eggs. This occurs in lakes and other places, like the one, they say, there was once around Cnidus, which was drying up at the time of the Dog Star, and all the mud was removed; water was starting to appear when the rains were coming. In it small fishes appeared as soon as the water was starting. They were a kind of mullet that did not come to be from mating at all, about the size of a small sprat; none of these contain either any egg at all or seminal fluid. In rivers in Asia too, which do not flow into the sea, other small fishes, about the size of those boiled for eating, come about in the same mode as these. Some people say that all mullets spring up in this way, but they are not correct; for females of these are also seen to contain eggs and males to contain seminal fluid. But there is a kind of mullet that springs up from mud and sand.

That some fishes come to be spontaneously, then, neither from eggs nor from mating, is evident from these cases. Those that are neither egg-laying nor live-bearing all come to be in some cases from mud, in some from sand, and from the putrefying on the surface—for example, the so-called foam (*aphros*) of fry comes to be from sandy earth. This fry (*aphuê*) never grows and is infertile, and after a certain amount of time, it is destroyed, and another springs up again. That is why, apart from a short period **$569^{b}1$** of time, it comes to be (one might almost say) in every season; for it lasts from the rising of Arcturus in the fall[362] until the spring. A sign that this fry sometimes comes up from the ground is that, when fishing, if the weather is cold, it is not caught, but if it is warm, it is caught, suggesting that it comes up from the earth for the heat. Also, when in dredging, the earth is being scraped up several times, the fry come to be in larger numbers and are of better quality. The other sorts of fry are of poor quality because of the rapidity of their growth.

The fry come to be in shaded and marshy places, when, after good weather has occurred, the earth is warming up—for example, in the neighborhood of Athens, at Salamis, and near the tomb of Themistocles, and at Marathon; for in these places the

360. 6.16.
361. 6.13–14.
362. Mid-September.

foam of fry occurs. It appears, then, in places of this sort and in good weather of this sort, but in some places when there is a lot of rain it also occurs in the foam produced by the rainwater, which is why it is called a "foam." {Sometimes too, when there is good weather, it is carried in on the surface of the sea, in which it collects; like larvae do in dung, so this does in the foam [of the sea], where it is composed on the surface; that is why this fry is often brought in from the deep sea. And the fry thrive and are caught in the largest numbers when the year is wet and warm.}[363]

The other sort of fry is the offspring of fishes: the so-called gudgeon fry is the offspring of the gudgeons that are small and of poor quality, the ones that burrow under the earth; from the Phaleron fry comes the *membras*, and from these the *trichis*, from the *trichis* the *trichias*, and from one sort of fry—for example, the one in the harbor of Athens, comes what is called the *egkrasicholos*.[364] There is also another sort of fry which is the offspring of the small sprats and mullets.

The infertile foam is watery and lasts only a short time, as was said previously;[365] for in the end a head and eyes are all that remain. However, fishermen have now found a way of transporting it; for when salted it keeps a longer time.

6.16
The Eels

The eels do not come to be from mating nor are they egg-laying, nor has one ever been caught which had either seminal fluid or eggs, nor when opened up do they contain seminal or uterine ducts. In fact, this whole kind of blooded animals comes to be neither from mating nor from eggs. It is evident that this is so; for in certain marshy pools, after all the water has been drained off, and the mud scraped out, the eels come to be again, when rainwater occurs; in droughts, on the other hand, they do not come to be, not even in stagnant pools; for in fact they live and are nourished by rainwater. It is evident, then, that they come to be neither from mating nor from eggs.

It seems to some people, though, that they do generate, because in some eels small worms appear; for they think that eels come to be from these. But this is not true: they come to be from the so-called entrails of the earth, which get composed spontaneously in mud and humid earth. In fact, eels have been observed emerging from these, and become visible when incisions are made and they are divided. Worms of this sort also occur in the sea and in rivers, especially when there is putrefying material: in the seas near the sort of places where there is seaweed; in rivers and mashes near their edges; for there the heat, being strong, causes putrefaction.

This, then, is the mode of generation of the eels.

364. The anchovy.
365. The reference seems to be to 569ᵇ1, but there a different point is made.

6.17
When Offspring Come to Be

The fishes do not all give birth in the same season or in the same way, nor are they pregnant for the same length of time. Before mating herds of males and females are formed, but when it is time for mating and giving birth, they form couples. Some fishes are pregnant for no more than thirty days, others for a shorter time; but all of them do so for a number of days divisible by seven. Pregnant for the longest time is the fish some people call the *marinos*. The sargus becomes pregnant around the month of Poseideon,[366] and is pregnant for thirty days. The mullet that some call **570^{b}1** the *chelôn*, and the *muxôn*, are pregnant in the same season and for same length of time as the sargus.

All the fishes suffer during pregnancy, that is why it is especially during this time that they are cast ashore; for, maddened by the pain, they get carried toward the land. And, in general, they continue to be in movement during this time, until they have laid their eggs. Among the fishes, it is especially the mullet that does this. When they have laid their eggs, they find rest. For many fishes there is an end to their pregnancy when larvae spring up in their abdomen; for certain small animate entities spring up and drive out the fetuses.

Offspring come to be in spring by the fishes that go in shoals with the current, and by most of them around the time of the spring equinox (by the other fishes, though, not in the same season of the year, but some in summer, others around the time of the fall equinox). The first of this sort of fish to lay eggs is the *atherinê*[367] (it lays them close to the land). The gray mullet is last; this is clear from the fact that the offspring of the former appear first, that of the latter last. The mullet is also among the first to lay eggs; the saupe does so mostly at the start of summer, but in some places in fall. The *aulôpias*, which some call the *anthias*,[368] also lays eggs in summer. After these are the gilthead, the bass, the *mormuros*, and, in general, the so-called migratory fishes.[369] Last among the fishes that live in herds are the red mullet and the sea crow;[370] these lay their eggs toward fall. The red mullet lays its eggs in the mud; that is why it lays them late; for mud stays cold for a long time. The sea crow lays eggs later than the red mullet, going out into the seaweed to do so, because it lives in rocky places; it is pregnant for a long time. The *mainis*[371] lay their eggs after the winter solstice. Among the others, the deep-sea dwellers mostly lay their eggs in summer; a proof of this is that they are not caught during this time.

366. Mid-November–mid-December.
367. Probably the sand smelt.
368. $620^{b}34$–$621^{a}2$.
369. $488^{a}6$.
370. Probably *Umbrina cirrosa*.
371. A Mediterranean variety of small sprat.

The most prolific of the fishes is the *mainis*, and of the selachians, the fishing frog (but these [fishes] are rare because [their eggs are] easily destroyed; for the eggs are laid in a mass and near the land). In general, the selachians are less prolific than the other fishes because they are live-bearing, but it is their offspring that mostly survive because of their size.

Also late in laying eggs is the so-called pipefish, and most of these, before laying them, burst open due to the eggs, which are not so much many in number as large in size. And like the venom-spiders, the offspring are crowded around the mother pipefish too; for she lays the eggs on herself; and if one touches them, they flee. The *atherinê* lays her eggs by rubbing her stomach against the sand.

The tunas burst open too, due to their fat. They live for two years. A sign of this is produced by the fishermen; for once when the young tunas failed to appear one year, the next year the adult tunas also failed to appear. It seems that these are a year older than the young tunas.

The tunas and the mackerel mate around the end of the month of Elaphebolion[372] and they lay eggs around the start of Hecatombaeon;[373] the eggs are laid in a sort of sac. The growth of the young tunas is rapid; for after the fishes have laid the eggs in the Black Sea, there comes from the egg what some people call *skordulai*, and the Byzantines call "growers (*auxidai*)," because of their growing (*auxanesthai*) within a few days; these leave in fall along with the female tunas, and return in spring, by which time they are already young tunas. Pretty much all the other fishes also grow rapidly, and all those in the Black Sea more rapidly still; for from day to day, in fact, the bonitos very noticeably grow.

In general, it is necessary to recognize that the same fishes, when not in the same places, do not have the same season either for mating, for pregnancy, for giving birth, or for good weather; thus, the so-called sea crows sometimes lay eggs around the time of the wheat harvest. What has been said, though, is aimed at stating what happens for the most part.

The conger eels also have embryos; but this is not equally noticeable in all places, nor, because of the fat, is the embryo very evident; for it appears elongated, as in the snakes.[374] But putting the eel on the fire makes it distinguishable; for the fat gets burned and melts, while the embryos jump around and make a noise when they explode. Further, if one touches it and rubs it in one's fingers, the suet feels smooth, the egg rough. Some of the conger eels have suet but no eggs, others, on the contrary, have no suet, but have an egg of the sort described just now.

372. February–March.
373. Mid-June–mid-July.
374. 558ᵇ1–2.

6.18
The Live-Bearing Terrestrial Animals: Horses, Cows, and Pigs

As regards the various animals that fly and swim, then, and as regards the terrestrial ones that are egg-laying, and about pretty much all of them, the mating, pregnancy, and other things similar to these have been spoke about. As regards all the terrestrial animals that are egg-laying, however, and as regards the human being, the corresponding things must now be stated in the same way. As regards mating, it was stated what is special and what is common to all.

Common to all the animals is to be excited by appetite and pleasure, especially those stemming from mating. The female animals are most bad-tempered just after they give birth, the males at mating time; for stallions bite other stallions and throw and chase their riders. But boars are the most bad-tempered—even though they are weakest at this time, due to mating—and engage in wondrous battles with each other, covering themselves in defensive armor and making their skin as thick as possible in preparation, by rubbing themselves against trees and repeatedly wallowing in mud and then drying themselves. They fight each other, driving each other from the herd in so violent a way that often they both get killed. Likewise, the bulls, the rams, and the male goats; for although beforehand they herd together, at mating time they fight and are at variance with each other. The male camel is also bad-tempered at mating time, if a human being or another camel comes near him; [and more when a horse does,] for it generally always fights with horses.

It is the same way in the case of the wild beasts; for the bears, the wolves, and the lions are bad-tempered with those who come near them at this time, though they fight less with each other, because none of these sorts of animals lives in herds. The female bears are also bad-tempered after giving birth to cubs, just as female dogs are after giving birth to pups.

The male elephants also become savage at mating time; that is why they say that in India the elephant keepers do not allow them to mate with the females; for they become so maddened at these times that they overturn their keepers' houses (since they are poorly built) and do a lot of other damage. They say too that an abundance **572^{a}1** of nourishment makes them tamer. Also, by introducing other elephants among them, they punish them and make them subject to themselves by commanding the ones introduced to strike them blows.

The animals that mate frequently and not at one season only—for example, those that live among human beings, such as pigs and dogs—are less evidently like this because of the frequency of their sexual intercourse.

Among the female animals, the most eager for copulation is the female horse, then the female cow. Female horses, indeed, are "mad-for-a-stallion (*hippomanein*)." (That is why, for purposes of defamation, their name is transferred from this one animal to those women who lack self-control as regards sexual intercourse.) They are also said to get impregnated by the wind around this time; that is why in Crete they never take

the mating males away from the females. When they are in this condition they run away from the other horses. (This is precisely the condition that, in the case of female pigs, is said to be "wanting the boar (*kaprizein*)".) And they run neither to the east nor to the west, but either to the north or to the south. When this condition occurs, they allow no one to come near them until they lose heart due to the exertion or reach the sea; at that point they expel something, like that found on the offspring they give birth to, which they call *hippomanes*.[375] It is like the sow-virus (*kapria*),[376] and the sorceresses seek it most of all.[377]

In mating season, the female horses huddle next to each other more than before, move their tail continuously, and emit a voiced sound quite other than at the rest of the time. A liquid flows from their sex organ that is like semen, but much finer-grained than that of the male; some people call this *hippomanes*, and not the one adhering to the foals. They say it is difficult to get; for it flows in small quantities. Also, they urinate frequently when they are in heat, and play with each other.

As regards the female horses,[378] then, this is the mode.

Female cows "want the bull," and are so violently possessed by this affection that the herdsmen are unable to control them or even to catch hold of them. Both female horses and female cows show it clearly when they are eager to mate by the swelling of their sex organs and—the female cows just like the female horses—by frequent urination. Further, the female cows mount the bulls and are always following them and standing beside them. The younger ones are the first to be eager for mating, both among the horses and among the cows; and when the weather is good and their bodies are in good condition, they are more eager.

When female horses are shorn, their impulse lessens and they become dejected. The male horses recognize the females of their herd by their odors, even if they have been together for only a few days before mating; and if others get mixed in with these, they bite them and drive them out. The males graze apart, each with his own females. Each is given around thirty females, or slightly more. When some male approaches, he assembles the females into the same compact body by running around them in a circle, then goes to do battle; and if one of them makes a movement, he bites and prevents her.

The bull, when it is mating season, begins to herd together [with the females] and fight other males (while beforehand they were together with each other); this is called "forsaking the herd": for often in Epirus, at any rate, bulls are not seen [in the herd] for three months.

In general, all or most males do not herd together with the females before mating season, but keep separate when they have reached maturity, and the males and the females feed apart.

375. 577[a]9, 605[a]2.
376. 573[b]2; ovaries at 632[a]21.
377. 577[a]12–13.
378. Reading τὰς ἵππους.

The female pigs too, when they are eager for mating (which is called "wanting the boar"), will thrust themselves even against human beings. In female dogs this sort of affection is called "being in heat."

A swelling of the sex organs occurs in the females when they are eager for mating and there is wetness around that place. Female horses squirt out a white liquid at this time.

Purgations of the menses occur in the females, but not to the same extent in any of the other animals as in women. In the sheep and the goats, when it is mating season, these appear as signs before mating; when they have mated, the signs still appear, then they cease for an interval, until they are about to give birth. Then they appear as signs again, and this is how the shepherds know that they are close to giving birth. When **573ª1** a female has given birth, the menses become copious; at first, it is not very bloody. Later on, however, it is very bloody. In the female cow, the female ass, and the female horse it is more copious because of their size, but in proportion to their size much less copious; thus the female cow, when eager for mating, is purged of a small quantity of menses, about a half-*cotyle* or a little less. The most opportune time for mating is when this purgation occurs. Among all the four-footed animals, the female horse gives birth most easily, best purges the postnatal discharges, and emits the least flow of blood, in proportion to the size of the body.

In the female cows and the female horses menses mostly appear at intervals of two, four, and six months; but it is not easy to discern without accompanying the animal and being very accustomed to it; that is why some people think that it does not occur in these animals.

In female mules menses do not occur at all, but the female's urine is more coarse-grained. In general, the residue from the bladder in the four-footed animals is more coarse-grained than in that of the human beings; in the sheep and the goats that of the females is even more coarse-grained than that of the males; but in the asses that of the females is finer-grained; that of the female cow is more acrid. After giving birth the urine of all the four-footed animals becomes more coarse-grained, especially in those whose purgation of menses is less.

The milk, once mating starts, becomes pus-like, but becomes usable after giving birth. When they are pregnant, both the sheep and the goats become fatter and eat more; the cows and all the other four-footed animals do the same thing.

The animals (one might almost say) in every case are more eager for mating in the season of spring; however, the time for mating is not the same for all, but is related to the appropriate times for the nourishment of offspring.

Tame female pigs are pregnant for four months and give birth to twenty offspring at the most; except that if they give birth to a lot, they are not able to rear them all. As they grow older, they continue to give birth in the same way, but are slower to mate. They conceive from a single mating, but they put the boar to the female pig many times, because after mating she discharges what some people call the "sow-virus." This happens **573ᵇ1** to all female pigs, but some emit the seed along with this. During pregnancy any one of

the offspring that gets damaged and deformed in respect of size is called an "after-pig"; this can occur in any part of the uterus. When the female pig has given birth, she gives her primary breast[379] to the first one.

When the female pig is in heat, she should not be put to the male immediately, not until she has dropped her ears; otherwise she gets in heat again; but if she is put to the male when she is eager, a single mating, as was said,[380] is enough. It is good to give the boar barley when he is mating, and boiled barley to the female pig when she has given birth. Among female pigs, some generate fine pigs only at the outset; others, as they grow, generate good offspring, that is, good piglets. Some people say that if the female pig has one of her eyes knocked out, she—for the most part—dies quickly. Most female pigs live for around fifteen years, but some reach a little short of twenty.

6.19
The Sheep and the Goats

Ewes conceive after three or four matings, but if it rains after the mating, they miscarry. It is the same with female goats. Most ewes give birth to two offspring, sometimes even three or four. Both the ewe and the female goat are pregnant for five months; that is why in some places that are warm and in which they thrive and have abundant nourishment, they give birth twice a year.

The goat lives for around eight years, the sheep around ten, though the majority live for less, except the leaders of the sheep; these even live for fifteen years. (In each flock they establish one of the males as leader. When he is called by name by the shepherd, he takes the lead. They accustom them to do this from an early age.) The sheep in Ethiopia live for twelve or thirteen years, the goats for ten or eleven. Both the sheep and the goat mate and are mated for as long as they live.

Both the sheep and the goats produce twin offspring due to abundant feeding; also, if the ram or the male goat is a twin-producer, or if the mother is. Some generate females, others males due to the water (for some waters are female-generating, some male-generating), and likewise due to the mating: those mated in north winds gen-
574a1 erate more males, in south winds more females. Female-generators can change and become male-generators: they must be faced north when mated. Those accustomed to being mated in the morning, if one tries to mate them in the evening, will not submit to the rams.

The offspring are born white or black in accord with whether the blood vessels under the ram's tongue are white or black: white if they are white, black if they are black; if they are both, both; if they are red, red. The ewes that drink salt water are

379. *PA* 688b8–14.
380. 573a34.

the first to be mated; they must be given salt before they give birth, when they have given birth, and again in spring.

The herdsmen do not establish a leader for the goats, because their nature is not stable, but hasty and changeable.

Among the sheep, if the older ones are eager for mating at the appointed season, the shepherds say that it is a sign of a good year for the sheep; if the younger ones are, that the sheep are in a bad state.

6.20
The Dogs

There are many kinds of dogs. Laconian hounds mate and are mated at eight months. And some dogs are already lifting their leg when urinating around this time. The dog conceives from a single mating; this is especially clear in cases where they mate secretly; for the females get pregnant after being mounted once.

The Laconian hound is pregnant for a sixth of a year (that is, sixty days), or perhaps one, two, or three days more, or one day less. Her puppies are blind when they are born and remain so for twelve days. After giving birth to them, she is ready to be mated again in six months, but not before. Some dogs are pregnant for a fifth of the year (that is, seventy-two days), and the puppies of these dogs are blind for fourteen days. Others are pregnant for a quarter of the year (that is, three whole months); the puppies of these dogs are blind for seventeen days. It seems, though, that the dog is in heat for the same length of time.

Menstruation in dogs lasts for seven days; at the same time swelling of the sex organ occurs. During this time they do not submit to mating, but rather in the seven days following; in fact, all of them seem to be in heat for fourteen days, for the most **$574^{b}1$** part; nonetheless, in some this affection lasts for around sixteen days. The postnatal purgation occurs at the same time as the birth of the puppies. It is coarse-grained and phlegm-like; its quantity, once they have given birth, becomes relatively minimal compared to their body.

The dogs have milk, for the most part, five days before they give birth; in some cases, however, it occurs seven days before, even four. It is usable immediately, once they have given birth. The Laconian hound has milk thirty days after mating. The milk at first is coarse-grained, but as time goes on it gets more fine-grained. Dog's milk is more coarse-grained than that of the other animals, after that of the female pig and the hare.

There is also a sign that a female has reached the age to be mated; for, just as in the case of human beings, a sort of swelling occurs in the nipples of the breasts and these have cartilage in them; nonetheless, it is not work for one not accustomed to it to observe these things; for the sign is of no magnitude.

This is what happens in the female. In the male none of this happens. The males lift their leg when urinating at the age of six months, for the most part. But some do it later, when they are already eight months, others before they are six months; simply speaking, it is when they start to have strength that they do this. The females all urinate sitting down, though some of them have been observed lifting their leg when they urinate.

The dog gives birth to at most twelve puppies; for the most part, five or six; but cases have been observed of a female giving birth to a single puppy. The Laconian hounds, for the most part, give birth to eight. Females are mated and males mate throughout life. A special affection of the male Laconian hounds is that they are more capable of mating after laboring than when they are idle.

The male Laconian hound lives for around ten years, the female for around twelve. Among the others, the females mostly live for around fourteen or fifteen years, some for as many as twenty; that is why some people think that Homer was correct to represent Odysseus' dog as having died in its twentieth year.[381] In the case of the Laconian hounds, because of the laboring of the males, the females are longer-lived than the males. In the case of the other dogs this difference is not very noticeable; the males are, nonetheless, longer-lived than the females.

The dog sheds no teeth except the so-called canines; these both the females and the males shed alike at the age of four months. Because they shed only these, some people dispute about it; for some people, because they shed only two, say that they shed none at all (for it is difficult to hit upon these [being shed]); others, when they do see these [being shed], think that they also shed all the others. People determine the ages of dogs from their teeth; for young dogs have white sharp teeth, while old dogs have black blunt ones.

6.21
The Cows

The male cow impregnates the female from a single mating; he mounts so violently that the female cow gets bent down. If he fails in his assault, the female must be allowed an interval of twenty days before mating again. The older bulls will not mount the same female several times in the same day, unless intervals are left between. The younger ones, by contrast, force themselves on the same female several times and mount many females, because of their vigor. The least lustful of the males is the bull, but it is the victor among the bulls that mates; but when, because of his lustfulness, he has become incapable, the defeated one attacks, and often overpowers him. The males first mate and the females are first mated, so as also to give birth, at one year;

381. *Odyssey* 17.326.

for the most part, however, it is at twenty months; the age most commonly agreed is two years.

The female is pregnant for nine months and gives birth in the tenth; some people confidently affirm that they are pregnant for ten months to the day. What is delivered earlier than the times mentioned is a miscarriage and will not live; for its hooves are soft and incomplete. She mostly gives birth to one offspring, seldom two; she gives birth and mates throughout life.

The females, for the most part, live for around fifteen years; the males too if they are castrated. Some live for twenty years, even more, if they have a healthy body; for in fact herdsmen train the castrated males and establish them as leaders of the herd, **$575^{b}1$** just as in the case of the sheep; these live for a longer time than the others because of not laboring, and because of having fresh pasture to graze on. The male is most in his prime at five years; that is why some people say that Homer is correct to speak of "a five-year-old male" and "a nine-seasons bull";[382] for these are equivalent.

The cow sheds its teeth at two years and, like the horse, not all at once. They do not shed their hooves when they have foot-disease, but only have very swollen feet.

The milk, once the female has given birth, becomes usable; before that she does not have milk. The first milk, when it has set, becomes as hard as a stone; this happens unless it is mixed with water.

Females younger than a year do not mate, unless there is something monstrous involved; but cases have been observed of being mated and mating even at ten months. Most females start mating around the month of Thargelion or Scirrophorion;[383] some, however, become pregnant as late as fall. When many are pregnant and submit to mating, it is believed to be a sure sign of stormy and rainy weather.

Females herd together as female horses do, but to a lesser extent.

6.22
The Horses

The male horse starts to mate at two years and the female to be mated at two years; but cases of this are few, and the offspring smaller and weaker. For the most part, the males start to mate, and the females to be mated, at three years; and until they reach the age of twenty years, the offspring get ever better. The female is pregnant for eleven months and she gives birth in the twelfth. The male horse does not impregnate her in a fixed number of days, but rather sometimes in one, two, or three days, sometimes in more; the ass when mounting impregnates more quickly than the horse. Mating is not burdensome for horses the way it is for cows. The most lustful animal—both of the females and of the males—after the human being is the horse. The mating of

382. *Iliad* 2.403, 7.315, *Odyssey* 19.420, 10.19.
383. May–June.

the younger ones occurs, contrary to their age, when they have good pasture and abundant nourishment. For the most part, the female gives birth to one offspring;
576ᵃ1 sometimes, however, to at most two. A female has been observed to give birth to two mules; people judge these to be monstrosities.

The male horse, then, mates at thirty months, so that he is fit to generate offspring when he has ceased shedding his teeth (but some have been observed to impregnate while still shedding, so it is said)—unless he happens to be by nature infertile. He has forty teeth. He sheds the first four at thirty months, two from the upper jaw, two from the lower. And again, when another year has passed, he sheds four others in the same way: two from the upper jaw, two from the lower. And again, when another year has passed, he sheds four others in the same way. When four years and six months have passed, he no longer sheds any. But one has been observed that immediately shed all his teeth at the same time as the first, and another that shed them all at the same time as the last; but things of this sort rarely occur. Hence it pretty much happens that when he is four years and six months, he is most useful for generating offspring.

Older horses are more generative of offspring, both the males among the males and the females among the females. Male horses mount both their mothers and their daughters; in fact, a herd is believed to be complete when the males mate with their own offspring.

The Scythians ride their pregnant female horses, as soon as the fetus has turned, and say that this makes them give birth more easily. The other four-footed animals give birth lying down, which is why the fetuses of all of them emerge sideways; but the female horse, when the time of delivery is near, stands upright to deliver her offspring.

Most male horses live for eighteen or twenty years, some for twenty-five or thirty; if one treats him with care, it may stretch out to fifty years. But the longest life for the majority of them is, for the most part, thirty years. The female, for the most part, lives twenty-five years, though some have been observed to live for forty
576ᵇ1 years.The males live for less time than the females because of their matings; and those that are raised on their own live longer than those in herds. The female attains her final length and height in five years; the male in six years. After that, in another six years, the animal attains its body mass, and improves until it is twenty years. The females reach maturity before the males, though in the womb the males do so before the females, just as in the case of the human beings;[384] the same thing happens in the case of all the other animals that do not give birth to many offspring.

They say that the female suckles the mule foal for six months, but then no longer submits to it because of being tugged at and caused pain; it suckles the horse foal for a longer time.

Both the horse and the mule are at their prime after the shedding of their teeth. When they have all been shed, it is not easy to know their age. That is why people say

384. *GA* 775ᵃ4–27.

they have a "mark of age" when they have not shed them; but when they have shed them, they do not have one. Nonetheless, the age can be most easily known, even after the shedding, from the canines; for in horses that are ridden they become small because of the friction (for the bit is inserted there); while those of horses that are not ridden are large and separate, while in young horses they are sharp and small.[385]

The male horse mates in all seasons and throughout life; the female too is mated throughout life, but not in all seasons, unless a halter or some other sort of compulsion is applied. There is no fixed season in which being mated and mating is excluded. Nonetheless, though mating may occur at any random time, it may not be possible to rear the offspring they have delivered. In a herd in Opus there was a horse that used to mate when he was forty years old, though he needed to have his front legs raised to do so.

Female horses start to be mated in spring. Once a female horse has given birth, she does not immediately thereafter become pregnant again but leaves an interval, and she gives birth to better offspring four or five years after giving birth. It is altogether necessary to leave interval of one year and to make her, as it were, fallow. **577^{a}1**

The female horse, then, gives birth only at intervals, as was said, but the female ass does so continuously.

Among the female horses, some are wholly infertile; some conceive, but cannot deliver an offspring; they say that a sign of this sort of condition is that, when the fetus is cut open, it has other kidney-like entities around the kidneys, so that it seems to have four kidneys. When the female horse has given birth, she eats up the chorion immediately and also eats off from the foal the growth on the foal's forehead called the *hippomanes*. In magnitude it is a little smaller than a dried fig; in appearance flat, round, and black. If anyone gets hold of it first and the female horse smells it, she gets deranged and maddened due to the odor. That is why indeed the sorceresses seek and collect it.

If a female horse that has been mated by a horse is mated by an ass, it destroys the already existing fetus.

The horse trainers do not establish a leader for the horses, as for the cows, because their nature is not stable, but hasty and changeable.[386]

6.23
The Asses

The ass mates and is mated at thirty months and sheds its first teeth. It sheds its second in six months, and its third and fourth likewise; they call these fourth ones its "mark of age."[387] A female ass has been observed to conceive at one year and be delivered of

385. Reading μικρός.
386. Reading διὰ . . . εὐκίνητον.
387. 576^{b}14.

an offspring. When she has been mated, she discharges the semen when she urinates, unless prevented; that is why people beat them immediately after mating and chase them around. She gives birth in the twelfth month. She mostly gives birth to one offspring; for she is by nature one-offspring-bearing; but sometimes she also gives birth to two.

An ass that mounts a female horse destroys the fetus of the horse, as was said.[388] But a horse does not destroy that of the ass, when the female horse has been mated by an ass. When pregnant, a female ass has milk at ten months. Seven days after giving birth, the male may be put to her, and she is most receptive of the impregnating agent on this day, though she may also take it in later. If she does not give birth before losing her mark of age, she never takes in the impregnating agent or conceives for the rest of her entire life. She is not willing to give birth if she is being watched by a human being or if she is in the light, and so they lead her into a dark place when she is about to give birth. She gives birth throughout life, if she gives birth before losing her mark of age. The ass lives for more than thirty years, and the female for more years than the male.

When a horse mates with a female ass or an ass with a female horse, there is far more often a miscarriage than when animals of the same kind have sexual intercourse with each other—for example, a horse with a horse and an ass with an ass. When a horse and an ass have sexual intercourse, the period of pregnancy is in accord with the male—I mean that birth occurs at whatever time it does in animals of the same kind [as the male]. But as regards the size of its body, its form, and its strength, the resulting offspring is made more like the female. If she is continuously subject to intercourse and certain intervals of time are not left in her being mated in this way, the female rapidly becomes infertile; that is why those involved in this business do not continuously bring them together to have intercourse in this way, but leave a certain interval of time. No female horse will admit a male ass (or a female ass a male horse), unless the ass happens to have been suckled by a female horse; for that reason, in fact, people put the ones called "horse-suckled" under a female horse. These mate in the herd when they overpower by force, just like the male horses.[389]

6.24
The Mules

The mule mounts and mates after shedding its first teeth, and at seven years it can even impregnate, and a case has been observed of a ginnus coming to be when a mule mounted a female horse. After that it no longer mounts. The female mule too has been observed to get pregnant, though not so as to carry the fetus through to the end. In Syria, in the part that is below Phoenicia, the half-asses[390] are mated and give birth; but their kind, though similar, is distinct from that of the mule.

388. 577a13–15.
389. 572b15.
390. 6.36.

The so-called ginni come to be from a female horse, when she is sick during pregnancy, just as in the human beings dwarfs come to be, and in the pigs after-pigs;[391] and ginni, like dwarfs, have a large sex organ.

The half-ass lives for many years; for one has been observed to have lived for as much as eighty years, as one did in Athens when they were building a temple; this animal was let go at that point because of its age, but by continuing to help in hauling and by accompanying the teams, urged them on to work, so that they passed a decree that the grain merchants not drive it away from their display trays. The female mule **578ª1** ages more slowly than the male. Some say that she purges her menses by urinating, and that the male ages more quickly because he smells the urine.

This, then, is the mode of generation of these animals.

6.25
The Ages of the Four-Footed Animals

Those having to do with the care of them know how to distinguish the young four-footed animals from the old ones: if when the skin on the jaw is pulled away it quickly goes back, the four-footed animal is young; if it stays wrinkled for a long time, the animal is old.

6.26
The Camel

The female camel is pregnant for ten[392] months, and always gives birth to one offspring only; for it is one-offspring-bearing. They take the offspring away from the camels at one year. The female camel lives a long time, more than fifty years. She gives birth in spring, and has milk until she holds a fetus in her womb. Her flesh and milk are the most pleasant tasting of all; people drink the milk mixing one part milk with two or three parts water.

6.27
The Elephant

The elephant first mates and is mated before the age of twenty years. When the female has been mated, she carries the fetus in her womb, some say for eighteen months, others say for three years. The cause of the non-agreement about the time is that it is not easy to observe the mating. The female gives birth while settling down on her

391. $573^{b}5$.
392. Cf. $546^{b}3$–4.

back parts, and is clearly in pain. When the calf is born, it suckles with its mouth and not with its trunk; it walks and sees as soon as it is born.

6.28
The Wild Pigs

The female wild pigs are mated at the start of winter and give birth in spring, when they retreat to impassable places that are especially precipitous, full of chasms, and thickly shaded. The male spends his time among the female pigs, for the most part, for thirty days. The number of the offspring and the period of pregnancy are the same as for the tame pigs. Their voiced sounds are much the same as of the tame ones, except that it is more often the female that voices them, rarely the male. Wild males that have been castrated grow larger and more bad-tempered, as Homer too says in
578b1 his poem: "He reared there a castrated wild pig: not like a grain-eating beast it was, but like a wooded peak."[393] They get castrated because when they are young they are attacked by an itching disease of the testicles; then they rub themselves against trees and squeeze out the testicles.

6.29
The Deer

The female deer is mated, as was said previously,[394] in most cases when withdrawing (for the female often does not submit to the male because of the tension [in his sex organ]); nonetheless they do sometimes submit to him and are mated like the sheep. When they are in heat, the females avoid each other. The male changes partners and does not spend his time with one female, but after leaving a short interval of time has sex with others. Mating occurs after the rising of Arcturus, around the months of Boedromion and Maemacterion.[395] The female is pregnant for eight months. She conceives in a few days after mating, and many are impregnated by a single male. For the most part, she gives birth to one offspring, but a few have been observed to give birth to two. She produces them beside roads, because of her fear of wild beasts.[396] The growth of the fawns is rapid. Purgation of the menses does not occur in female deer at other times; when they give birth, a phlegm-like purgation is produced.

They customarily lead the fawns to lairs, that is, a place of refuge for them; this is an inaccessible cave with one entrance, where they customarily defend themselves against attackers.

393. A mix of *Iliad* 9.539 and *Odyssey* 9.191.
394. 540a5.
395. I.e., in October.
396. 611a15–17.

Stories are told about the life of the deer implying that it is long-lived, but it is evident that none of the stories is at all perspicuous, and the pregnancy and the growth of the fawns do not take place as if the animal were long-lived.

On the mountain called "Deer Mountain," which is in Arginussa in Asia, where Alcibiades died, all the female deer have their ear split, so that even if they wander far afield they can be recognized by this; their fetuses while still in the womb already carry this sign.

The females have four nipples like the female cows. After the females have been impregnated, the males separate off by themselves, and because of the impulse of their sexual desires, each one when left solitary digs a hole, and stinks[397] like the male goats. And their faces become black because of being splattered,[398] like those of the male goats.[399] They spend their time in this way until the rain comes; after that they return to pasture. The animal does these things because of being lustful by nature and because of its fatness; for the fatness of these animals becomes excessive in the summer; that is also why they are unable to run, but are caught by hunters on foot in the second or third chase, and flee toward the water because of the heat and their panting for breath. At the time when they mate, their flesh becomes of poor quality and foul-smelling, like that of the male goats. In the winter they become thin and weak, but toward spring they are most at their peak for running. When they flee, they make a pause in their running, and stand still until their pursuer draws near; then they flee again. They seem to do this because of being in pain internally; for they have an intestine that is so thin and weak that, if one gently strikes the animal, it breaks open, although their skin remains sound. **579^{a}1**

6.30
The Bears

The female bears are mated, as was said previously,[400] not by being mounted but when they are lying on the ground. The female bear is pregnant for thirty days; she gives birth to one or two offspring, at most five. She gives birth to a fetus that is the smallest in comparison to the size of her own body; for it is smaller than the one a weasel gives birth to, but larger than a mouse, is hairless and blind, and its limbs and most of its parts are pretty much unarticulated.

The female is mated in the month of Elaphebolion,[401] and gives birth around the season for going into hiding. Around this time both the female and the male become

397. Reading βρομεῖ. Alternatively, βρωμᾶται ("bellows").
398. Perhaps with mud or sweat from digging.
399. Reading τὰ τῶν τράγων.
400. $539^{b}33$–$540^{a}2$.
401. February–March.

very fat. When the female has reared her offspring, they show themselves in the third month, and it is already spring.

The female porcupine also goes into hiding and is pregnant for an equal number of days, and in all other respects is like the female bear.

It is a task to capture a pregnant bear.

6.31
The Lions

The lion mates back to back, and urinates backward, as was said previously.[402] It does not mate and give birth in every season, but once each year. It gives birth in spring and, for the most part, gives birth to two offspring or at most six; but sometimes it gives
579[b]1 birth to only one. The story told about the expulsion of the uterus after giving birth is silly; it was contrived because of the rarity of lions, and because the one who contrived the story was at a loss as to the cause; in fact, the lion kind is rare and does not occur in many places, but in all of Europe is found only between the rivers Achelous and Nessus. It gives birth to such altogether small offspring that at two months they can hardly walk. The ones in Syria give birth five times; first to five offspring, then always to one fewer; after that they no longer give birth to any, but remain infertile to the end.[403]

The lioness does not have a mane, but the male lion does. Of his teeth, the lion sheds only the four so-called canines, two from the upper jaw and two from the lower; it sheds them at six months.

6.32
The Hyenas

The hyena is wolf-like in color, but it is hairier, and has a mane the whole length of its spinal column. What is said about its sex organs, that it has that of a male and that of a female, is false. In fact, the male has one like that of the wolves and of the dogs; and has the one that seems to be characteristically female under his tail: it is much the same in shape as that of the female, but it does not have any duct; and underneath it is the duct for the residue. The female hyena also has what is said to be similar to the female's sex organ; like the male, it has it underneath the tail, but it has no duct; after this is the duct for the residue, and underneath this is the true sex organ.

The female hyena also has a uterus like all the other female animals of this sort. It is a rare thing to catch a female hyena; among eleven hyenas, at any rate, a hunter said he caught only one female.

402. 539[b]22.
403. *GA* 750[a]31–35.

6.33
The Hares

The hares are mated by having intercourse back to back, as was said previously[404] (for the animal urinates backward). They are mated and give birth in all seasons. They are subject to superfetation when they are pregnant; they give birth every month. They do not give birth to their offspring all together, but leave an interval of as many days as it happens to be. The female has milk before giving birth, and after giving birth is **580ª1** immediately mated; she conceives while suckling her offspring. In coarse-grainedness the milk is like that of the pig. She gives birth to blind offspring like most of the multi-split-footed animals.

6.34
The Foxes

The fox mates by mounting the female, who gives birth like the bear, and to even more unarticulated offspring. When she is about to give birth, she goes off to a remote place, so that it is a rare thing to catch a pregnant one. When the offspring have been born, it is by licking them with her tongue that she warms them and completes their concoction. She gives birth to four at most.

6.35
The Wolf, the Cat, and Others

The wolf is pregnant and gives birth like the dog both in time and in the number of offspring that come to be, and, like the dog, it gives birth to blind ones. It mates and is mated in a single season, and gives birth at the start of summer. There is a sort of account stated about the wolf's giving birth that borders on myth; for they say that all wolves give birth in twelve days of the year. The cause of this is in the myth they state: because in that many days did they transport Leto from the land of the Hyperboreans to Delos, while she took on the appearance of a she-wolf because of her fear of Hera. Whether this is the time of their giving birth or not, no one has up to now, at any rate, been able to observe, but only that it is what is stated. On the other hand, the saying that wolves give birth only once in their live is manifestly not true.

The cats and the ichneumons give birth to as many offspring as the dogs, and nourish them in the same way. They live for around six years.

The panther also gives birth to blind offspring like the wolf, and gives birth to four at most.

404. $539^{b}22$–24.

The *thôs*[405] conceive like the dogs, and give birth to blind offspring; in number, they give birth to two, three, or four. The *thôs* is in form long [from head] to tail, but relatively shorter in height. It is similarly remarkable for its speed, even though its legs are short, because it is supple and makes long leaps forward.

6.36
The Half-Asses

580b1 In Syria there are so-called half-asses, which are distinct in kind from the ones that come to be from the copulation of a horse and an ass, though as similar to them in appearance as the wild asses are to the domestic ones; they derive their name from the similarity. The half-asses, like the wild asses, are remarkable for their speed. These half-asses generate offspring among themselves. A sign of this is that some of them came from Phrygia in the time of Pharnaces, the father of Pharnabazus, and the half-asses still remain there. There are three of them now, but formerly there were nine, so they say.

6.37
The Mice

The generation of mice is most wondrous compared to that of the other animals, both in numbers and the rapidity. For a case has been observed of a pregnant female that was once locked up in a jar of millet seed; after a short time, when the jar was opened, the number of mice that appeared was one hundred and twenty.

A puzzle also arises about the generation of mice on the surfaces of fields and their disappearance; for in many places an untold number of field mice customarily appear, with the result that little is left of the entire crop of grain. Their reproduction is so rapid that some farmers, who work on farms that are not that large, having seen on the previous day that it is time to reap the harvest, find, on leading the reapers out at dawn the next day, that the entire crop has been eaten. Their disappearance too is unaccountable; for in a few days they disappear altogether; and yet before that the people failed to control them by fumigating them, digging them out, hunting them, and setting the pigs on them (for these dig up the mouse holes). The foxes also hunt them, and the wild ferrets in particular destroy them, when they fall upon them; but they have no control over their fecundity and rapid reproduction, nor does anything else except the rain, when it falls upon them. Then they disappear rapidly.

405. 507b17.

There is a place in Persia where, when a female mouse is cut open the female fetuses are seen to be pregnant. Some people say—indeed strongly contend—that if the females lick salt they become pregnant without mating.

The mice in Egypt have hard hair like the hedgehogs. There are other mice that **581a1** walk on two legs; for they have small front legs and long back ones; they come to be in great numbers. There are also many other kinds of mice.

BOOK 7[406]

7.1
Puberty in Human Beings

As regards the development of the human being, first inside the female and afterward until old age, all that happens due to the animal's own proper nature does so in the following way.

The difference between the male and the female and their parts was stated previously.[407] The male starts to have seed, for the most part, when fourteen years have been completed. At the same time, the growth of the pubic hair starts, just as plants that are about to have seed produce flowers first, as Alcmaeon of Croton says. Around this same time, the voice starts to change, becoming harsher and more uneven, neither high-pitched nor deep as yet, nor entirely even, but sounding like strings that are badly strung and harsh: what they call "bleating like a goat." This occurs more in those trying to have sexual intercourse; for in those who are eager for this, the voice changes to the voice of a man, while in those who abstain from it, the contrary happens. If they assist in holding themselves back through exercises, which is precisely what some do who are serious about belonging to choruses, their voice stays as it is for a long time and the change that it undergoes is altogether small.

Also a swelling of the breasts and of the sex organs occurs, which change not only in size but also in form. And around this time, in those who try rubbing in connection with the emission of seed, not only does pleasure occur when emitting seed but pain too.

Around the same time, in the female a swelling of the breasts occurs and the so-called menses flow down; this is blood like that of a newly slaughtered sacrificial **581b1** victim.[408] (The whites[409] occur also in children who are altogether young, especially if they are furnished with liquid nourishment; it prevents growth and emaciates the children's bodies.) The menses occur in most females when the breasts have risen two

406. Book 7 is placed after Book 9 in many manuscripts. Its authenticity has been questioned.
407. 3.1.
408. A common analogy in the Greek world.
409. Leucorrhea.

finger-widths. And the voice in girls also changes for the deeper around this time. For while a woman's voice is, in general, higher-pitched than a man's, younger women's voices are higher-pitched than older women's, just as boys' ones are higher-pitched than men's; but the female children's voice is higher-pitched than the male children's, and the maiden's pipe higher-pitched than the boy's.

Female children are most in need of guarding around this time; for they are most impelled toward pleasures of sexual activities when these start, so that unless precautions are taken to prevent causing movement that goes further than the one their bodies make in changing, without being involved in sexual activities, they are habituated in following them into later life. For the females who engage in sexual activities while altogether young become more intemperate, and so do the males, if they are unguarded either in one direction or in both;[410] for the ducts become dilated and make the body open-ducted in this part;[411] and at the same time the memory of the pleasure that accompanied them then produces an appetite for the sexual intercourse that then occurred.

Some men are impuberal from birth and infertile because of a deformation in the genital area; likewise some women too are impuberal from birth.

The males and the females also change in their conditions, as regards being healthier or sicklier, and as regards the leanness, fatness, and well-nourishment of their body; for, after puberty, some males change from being thin to being fat and become healthier, while others do the contrary; this happens in the same way in girls too. For all boys and all girls that are full of residues, when such things are secreted along with the seed or the menses respectively, their bodies become healthier and better nourished with the discharging of the things that hinder health and nourishment; in all the contrary cases, their bodies become thinner and sicklier; for the secretion in the seed or in the menses comes from the nature and good conditions of the body.

Further, in the case of girls, the breasts also differ from one girl to another; for some have altogether large ones, others small ones. For the most part, the former comes about in all those who were full of residues in childhood; for when the menses are due but have not yet come, the more liquid there is, the more it compels [the breasts] to swell up, until [the menses] have flowed down; the result is that the breasts acquire bulk at that time and remain that way later on as well. In the males too the breasts become more noticeable and womanlike in those, both younger and older, whose constitution is liquid, smooth, and without large blood vessels, and who are dark rather than pale.

Up to the age of twenty-one years the seeds are at first infertile; then, though they are fertile, the offspring of young men and young women are small and incomplete, as they are in the case of most of the other animals.

410. I.e., as active partners or as passive partners (†*Pr.* 4.26).
411. †*Pr.* 4.11.

The young females conceive more quickly, but, when they have conceived, they suffer more in giving birth. Also, their bodies develop less completely, for the most part, and age faster, both in those men who are lecherous and those women who give birth too many times; for it seems that no further growth occurs either after the third giving birth.

All women who are intemperate in relation to sexual intercourse settle down and become more temperate after giving birth several times. After their twenty-one years, women are in a condition favorable to childbearing, while men continue to improve.

It is the fine-grained seeds that are infertile, while the more granular are fertile and more male-generating; those that are fine-grained and unclotted generate females.

Also, a growth of chin hair occurs in men around this same age.

7.2
The Menses

The onset of the menses occurs toward the end of the month; that is why some of those who deal in sophistries say that the moon too is female, because the purgation of the menses and the moon's waning occur together, and after the purgation and the waning both become filled up.[412] In women it is rare that the menses occur regularly every **$582^{b}1$** month; in most cases, they occur in the third month.[413] Those in whom they occur for a short time, two or three days, recover easily, while those in whom they last for many days have more difficulty. For they suffer during those days; for though in some the purgation of the menses occurs all at once, in others little by little. In all of them the body is distressed until they are discharged. In many women, when the menses are starting and about to burst out, choking feelings and noise are produced in their uterus, until they have burst out.

By nature conception occurs in women after recovery from these; and the ones in whom they do not occur remain childless, for the most part. Nonetheless, even without their occurrence, some do conceive. These are all the ones in whom as much moist secretion is collected as remains after the purgation of the menses in fertile women, but not enough to be discharged outside. Some also conceive while the menses are still occurring but do not conceive after them: these are the women whose uterus closes up immediately after the purgation. In some women the menses are produced throughout their pregnancy up to the end; the result, however, is that they give birth to inferior offspring, and their offspring either do not survive to grow or grow up weak.

412. *Plêrôsis* means both "filled up" and "pregnancy."

413. If menstruation occurs in month one, the next menstruation mostly occurs not in month two, but in month three. In other words, the interval between menstruations is more than four weeks. The months are lunar months.

In many women too, because of their need for sexual intercourse, either due to their youth and time of life or to long abstinence, the uterus descends below and the menses are often produced three times a month until they have conceived; then the uterus returns to its proper place above. But sometimes, even if the uterus is in good condition, but happens to be wet, it blows out[414] the wetter part of the seed.

Among all the animals, as was said previously,[415] it is in women more than the other females that the most purgation is produced. For in the non-live-bearing animals no sign[416] of this sort appears, because this residue is diverted into the body (for some are larger than the males, and further, in some it is used up in hard-scales, in some in soft-scales, and in some in a mass of feathers), while in the footed live-bearing ones it is diverted into the hair and the body (for the human being is the only smooth one), and into urine (for in most animals of this sort the secretion produced is coarse-grained and copious); but in women the residue is diverted into the purgation instead of these.

It is likewise in the case of men; for in proportion to his size, the human being emits the most seed compared to the other animals (that is also why the human being is the smoothest of the animals), and of these, the ones whose natures are wetter and not very fleshy, and the paler ones more so than the darker ones. It is the same way in the case of women. In the well-fleshed ones, most of the secretion goes to nourish the body. And in sexual intercourse those who are paler in nature exude more liquid than the dark ones. And the liquid and bitter sorts of nourishment produce more of this sort of effect in sexual intercourse.

7.3
Conception

A sign that women have conceived is when the place is dry immediately after sexual intercourse. If the lips of the mouth [of the womb] are smooth, they are not suited to conception (for the seed slips out), nor if they are thick. But if to the touch of a finger the lips feel rather rough and clingy, and if they are thin, they are in a condition favorable to conception. For purposes of conception, then, this is the condition one must establish the uterus in; for purposes of non-conception, the contrary one; for if the lips are smooth, conception does not occur; that is why some people oil that part of the womb on which the seed falls with cedar oil, white lead, or frankincense, diluted with olive oil. If the seed stays in for seven days, it is evident that it has taken hold; for what are called "effluxions"[417] occur during these days.

414. 635ᵇ4–5.
415. 521ᵃ25–27, 572ᵇ29–31.
416. 572ᵇ32–573ᵃ2.
417. 583ᵇ11–12, *GA* 758ᵇ5–6.

The purgations recur in most women at a certain time after conception, at thirty days at most in the case of female fetuses, at around forty days in the case of male ones. After the births too the purgations tend to recur at the same number of days, though not indeed with equal exactness in all women. But after conception, and the days just mentioned, it is no longer natural for them to occur, but they are diverted into the breasts and become milk. The first sign of milk appearing in the breasts is small in quantity and filled with filaments.

When women have conceived, a perception of it occurs especially in the flanks (for in some women these immediately become fuller; this happens more noticeably in thin women) and in the groin. In the case of male fetuses, their movement occurs more on the right side, for the most part, at around forty days, in that of female fetuses on the right side at around ninety days. Nonetheless, one must not suppose that there is any exactness in these things; for in many who give birth to a female the movement occurs on the right, and in those in whom it is on the left to a male. But these and all things of this sort differ, for the most part, with respect to the more and less.

Around this time too the embryo divides into parts, while previously it consisted of unarticulated fleshy material. Those that are destroyed at up to seven days are called "effluxions," those at up to forty days "miscarriages." It is during these days that most embryos are destroyed.

The male embryo, when it emerges at forty days, although if one puts it into anything else it dissolves and disappears, if one puts it into cold water, it gets composed as if in a membrane; and if incisions are made in this membrane, the fetus appears the size of one of the big ants: all its members are clear to perception, as well as the other parts, especially the sex organ, and the eyes—as in the case of the other animals—are very large.

The female embryo that is destroyed within three months appears unarticulated, for the most part. One that has reached the fourth month has divided into parts and quickly attains the rest of its articulation. For a time, then, the female is slower to attain the complete development of its parts than the male, and is more often born at ten months than the male. But when they are born, the females are quicker than the males to reach youth, prime of life, and old age, especially those who have given birth a large number of times, as was said previously.[418]

7.4
Pregnancy

After the uterus has conceived the seed, it immediately closes up in most women until seven months have occurred; in the eighth it opens up, and the fetus, if viable, descends in the eighth month. Those that are not viable but have suffocated at eight

418. $582^{a}21–25$.

months, women do not expel them by giving birth at eight months, nor do the fetuses descend in the eighth month, nor does the uterus open up at this time. In fact, it is a sign that the offspring is not viable, if it has been born without the circumstances just mentioned being present.

After conception, women feel oppressed in their entire body, have darkness in front of their eyes, and pains in their head. These develop more quickly in some women, pretty much at ten days, in others more slowly, in accord with whether they happen to be more or less productive of residues. Further, bouts of nausea and vomiting attack most women, especially women of the former sort, when the purgations cease but have not yet been diverted to the breasts. Some women, then, suffer more at the start, some later on when the embryo has already acquired more growth; in many too stranguries occur at the end.

For the most part, those that conceive males recover more easily [from these complaints], and end up with a better complexion, but in the case of those who conceive females it is the contrary; for they have worse complexions, for the most part, spend their time feeling more oppressed, and in many tumors in the legs and swellings of the flesh occur; nonetheless, in some women the contrary things occur too.

It is usual for all sorts of appetites to occur in pregnant women and for them to change abruptly, which is what some people call "having cravings."[419] In the case of [those pregnant with] females, the appetites are sharper, but when the things are at hand they are less able to indulge them.[420] In a few women, it happens that the body is in better condition when they are pregnant. Also, they glut themselves most[421] when their babies start to produce hair. Also, in pregnant women the hair that is congenital becomes sparser and falls out, but in places where they are not accustomed to have hair it grows more thickly.

Also, for the most part, the male [fetus] exhibits more movement when inside the body than the female, and is born more quickly, the female ones more slowly. Also, labor in the case of the female ones is more continuous and more gradual, while in the case of the male ones, while it is more abrupt, it is more difficult. Women who have sex with men before giving birth give birth more quickly. Sometimes women seem to be in labor not because labor is occurring but because the fetus turns its head, and this appears to be the start of labor.

In the other animals the completion of giving birth is accomplished in one way only; for a single time of giving birth is determined in all animals; but for the human being alone among the animals there are many times; for seven-month, eight-month, and nine-month ones occur, and in most cases ten-month ones; but some women even reach the eleventh month.

419. Literally, "having ivy-sickness."
420. Because of feeling more oppressed and so on.
421. Alternatively, "they are most nauseated or disgusted."

All the offspring that are born before the seventh month can in no circumstances live. The seven-month ones are viable first, but many of them are weak (and that is why people swaddle them in wool), and many of them have some of their ducts undivided, such as those of the ears and the nostrils; but as they increase in size these become divided, and many babies of this sort live. As for the eight-month ones, around Egypt and in some places where the women are good at bearing offspring, and easily bear and bring to birth many, and where, when they have been born they are able to live, even if they are monstrous births, in those places the eight-month ones live and are reared, while in the places around Greece altogether few survive, while the majority perish; and because of the supposition [that this is the norm], even if one does survive, they think that the offspring is not an eight-month one, but instead take it that the women themselves had conceived earlier without knowing it. **584ᵇ1**

The women suffer most in the fourth month and the eighth, and if they abort in the fourth month or the eighth, for the most part, they themselves also perish; as a result, not only do eight-month offspring not live, but when they are aborted the women who give birth to them are also put at risk.

In the same way, it seems, the same error is committed when offspring appear to be born later than the eleventh month; for in their case too the start of conception escapes the notice of the women; for often when their uterus had previously become distended with air, and later they had sex and conceived, they think that the former was the start of conception, because it furnished them with similar signs.

This is the difference in number, then, in the ways the giving of birth is accomplished on the part of the other animals compared to human beings; also, while some of them are one-offspring-bearing and others many-offspring-bearing, humankind plays a double game. For although in most cases and among most peoples women give birth to one offspring, often and in many places they give birth to twins—for example, around Egypt. They even give birth to three or four, especially in certain places, as was said previously.[422] The greatest number given birth to is five; for this has already been observed to happen in several cases. One woman produced twenty in four births; for she gave birth to five at a time, and most of them were reared.

In the other animals, even if the twins are a male and a female, they are reared after birth, and are no less likely, when born, of being reared and of surviving than [twin] males or females; among human beings, on the other hand, few twins survive if one is female and the other male. **585ᵃ1**

Among the animals, the woman and the female horse are the most receptive of mating while pregnant; the others when pregnant avoid the males, except for all the ones in which superfetation is natural, like the hare. But the female horse, if she has

422. 584ᵇ7.

conceived the first time, does not do so again by superfetation, but, for the most part, gives birth to only one offspring, while in the human being, though superfetation is rare, it has sometimes occurred.

Those, though, that are conceived by superfetation a long time later do not reach completion, but after producing pain cause the preexisting fetus to be destroyed along with themselves (for a case has been observed where, after a miscarriage, no less than twelve embryos conceived by superfetation fell out). But if the second conception occurred soon after, mothers have brought the superfetation to birth, and given birth as to twins from the same semen, as in the myth about Iphicles and Heracles. For that that has in fact happened is evident. For an adulterous woman gave birth to one child like her husband and another like the adulterer. And a woman already pregnant with twins conceived a third by superfetation; when the normal time had come, she gave birth to the former as full-term babies and to the latter as a five-month one; and this one died immediately. And to another woman it happened that she gave birth first to a seven-month baby and later to two full-term ones; and of these the first died but the second ones lived. And some women have conceived at the same time as they miscarried and lost the one but gave birth to the other.

In most women, if they have sexual intercourse after the eighth month, the baby emerges covered in a viscous mucus-like liquid. And often it appears covered in the foods that the mother has been given. And when the mothers have used too much salt, the babies are born without nails.

7.5
Fertility (1)

The milk that occurs before seven months is useless; but at the same time as babies become viable, the milk becomes useful. The first milk is also salty, as in sheep. During pregnancy most women are especially sensitive to wine; for they get relaxed, if they drink it, and lack strength.

The start of giving birth to offspring in women and of begetting them in males, and their cessation in both, is the emission of seed in the males and of menses in the women, except that they are not immediately fertile when the emissions start, nor any longer so when these become few and weak. The age at which they start has been stated.[423] The menses cease in most women at around forty years, but in those in whom they exceed this time, they last until fifty years. And some of these have been observed to give birth; but none at a later time.

423. 581a13, 31.

7.6
Fertility (2); Resemblance between Parents and Offspring

Most men generate offspring up to sixty years; when they exceed that, up to seventy years; and some men have been observed to generate offspring at seventy years.

It happens to many men and many women that they are unable to produce children when coupled with each other, but can when coupling apart. The same thing also happens as regards generating males and generating females; for sometimes both women and men are male-generating or female-generating with each other, but become the contrary when coupling apart. And they also change with age; some generate females with each other when they are young, but males when they are older; in others the contrary also happens in this regard. And in the case of generating, in general, it is the same; in some no offspring comes to be when they are young, but rather when they are older; others generate at first, but generate no offspring later.

There are also some women who conceive with difficulty, but if they do conceive, bring the offspring to birth; others, on the contrary, conceive easily but cannot bring the offspring to birth. And there are men who generate females and women who generate males, as, for example in the myth about Heracles who in seventy-two offspring generated one daughter. Women who are unable to conceive unless through receiving treatment or through some other sort of circumstance are, for the most part, female-generating rather than male-generating. It also happens that many men who are able to generate offspring are later unable to do so, and then have it restored again.

From deformed parents deformed offspring are also born—for example, lame ones from lame ones and blind ones from blind ones, and, in general, offspring that often resemble them in their contrary-to-nature features, and possess signs akin to theirs—for example, growths and scars. And cases have been observed of something of this sort returning in the third generation—for example, a man had a mark on his arm that his son was not born with, but that his grandson had in the same place, blurred and dark.[424] Things of this sort, though, seldom occur, and in most cases from docked parents non-docked offspring are born, and nothing about these is fixed. There are also offspring who resemble their parents or their distant ancestors, but sometimes they do not resemble any. But it may return after several generations—for example, the woman in Sicily who committed adultery with the Ethiopian; for her daughter was not born an Ethiopian,[425] but her daughter's offspring was.

For the most part, females more resemble their mother, males their father; but the contrary also occurs, females resembling their father, males their mother. And with respect to the parts too, resemblances occur to the parts[426] of each. And cases have been observed of twins born that did not resemble each other, but for the most part,

424. *GA* $721^{b}28$–$722^{a}1$.
425. I.e., black.
426. Retaining μέρη.

most are alike; thus, even after giving birth, a woman—who a week later had sexual intercourse and conceived—gave birth to a second child as like the first as a twin. There are also women who generate offspring who resemble themselves, while others generate ones that are like the man, as did the mare of Pharsalus called "the Just."[427]

7.7
The Emission of Male Seed

In the emission of seed, it is first preceded by breath (the emission shows clearly that it occurs due to breath; for nothing is thrown to a distance without a force of breath). When the seed has taken hold of the uterus and has remained inside for a time, a membrane surrounds it; for when it emerges before it has become articulated, it looks like an egg encompassed in a membrane after its shell has been removed; the membrane is full of blood vessels.

All the animals that swim, fly, or walk, whether live-bearing or egg-laying, come to be in the same way, except that in some (the live-bearing ones) the umbilical cord goes to the uterus, in some to the egg, and in some to both—for example, certain kinds of fishes.[428] Some have [the seed] encompassed by a membrane, others by the chorion. First the animal develops within the innermost membrane, then another membrane develops around this one, mostly attached to the womb, but partly detached, and containing water. In between the two is a liquid that is watery or sanguineous, which by women is called the "forewaters."

7.8
The Fetus and the Umbilical Cord

All the animals that have a navel grow by means of the umbilical cord. The umbilical cord, in all those that have cotyledons, is attached to the cotyledon, while in those whose uterus is smooth it is attached to the uterus at a blood vessel. As for their shape within the uterus, the [fetuses of the] four-footed animals all are stretched out, the footless ones are on their sides (for example, the fish), and the two-footed ones
586[b]1 are bent up (for example, the bird); the human being too is bent up, and has the nose between the knees, the eyes on the knees, and the ears outside them. All animals alike have the head up at first; as they grow and start to move toward the outlet, they turn downward, and birth in accord with nature is head first, though some are born bent up and feet first contrary to nature.

427. *Pol.* 1262[a]24.
428. The selachians, 565[b]2–9, *GA* 754[b]27–33.

The fetuses of the four-footed animals contain residues too, when their development is complete, both liquid and lumps of dung, the latter in the extremity of the intestine, the urine in the bladder.

In those animals that have cotyledons in the womb, the cotyledons become ever smaller as the fetus grows, and in the end disappear.

The umbilical cord is a sort of sheath around blood vessels, the starting-point of which is from the uterus (from the cotyledons in those that have cotyledons, from a blood vessel in those that do not have them). In the larger animals (for example, in the fetuses of cows), there are four blood vessels, in the smaller ones two, and in the altogether small ones (for example, in the birds) only one blood vessel. These extend to the fetuses, two going through the liver (where the so-called portals are[429]) to the great blood vessel, and the other two through to the aorta where it divides, and the aorta, from being one, becomes two. Around each pair of blood vessels there are membranes, and around the membranes, like a case, is the umbilical cord. The fetus, as it matures, goes into the hollows [of the uterus] and there its movement is clear to perception, and sometimes it rolls over in the area around the sex organ.

7.9
Labor

When women are in labor, their pains are confirmed by them in many other parts but mostly in one or the other of their thighs. All those whose pains are most intense around the stomach are the quickest to give birth; all those who suffer first in the loins give birth with difficulty, but all those who do so in the lower abdomen are quick.

If they give birth to a male, the preceding discharges of serum are watery and yellowish; if they give birth to a female, they are bloodlike, but also watery; but in some neither of these occurs during labor.

In the other animals giving birth is not painful, although to a more moderate extent, they are noticeably troubled by labor; but in women the pains occur with more strength, especially in sedentary ones and those who do not have strong lungs and are not able to hold in their breath.[430] They suffer more in giving birth in fact, if they breathe out in between, when they are trying to exert force with the breath. First to emerge, then, is a watery discharge, when the fetus starts to move and the membranes are being broken open, then the fetus emerges while the uterus is being inverted, and what was inside the uterus is outside.

429. $496^{b}32$.
430. *GA* $737^{b}35$–$738^{a}1$.

7.10
Cutting the Umbilical Cord

The cutting of the umbilical cord by the midwife requires thought if it is not to miss the mark; for not only must she be able to help with women's difficult births with her skillful hand, but she must also have the acumen to deal with contingencies, especially as regards the tying of the umbilical cord of babies. For if the afterbirth has also emerged, the umbilical cord is ligatured off from the afterbirth with wool, and is cut above the ligature; and at the place where it has been ligatured, it grows together, and the adjoining part falls off. (If the knot comes untied, the fetus dies from the blood's running out.) But if the afterbirth has not immediate emerged, but remains inside when the baby itself is outside, it is cut away after the ligaturing of the umbilical cord. Often the baby has seemed to be born dead, when—being weakly before the umbilical cord has been ligatured—blood has run out into the umbilical cord and the surrounding part by luck; but certain midwives who are skilled in the craft have been observed to squeeze the blood from the umbilical cord back inside, and immediately the baby, that had previously become as if bloodless, came back to life again.

As was said previously,[431] the other animals too are born, in accord with nature, head first, but babies also have their hands stretched out by their sides. After coming out, they immediately utter a cry and bring their hands up to their mouths. They also emit residues, some immediately, others soon after, but all within a day; and these are very large in quantity considering the size of the child; it is what the women call the "meconium." Its color is bloodlike, very black and pitch-like, but after this it becomes milk-like; for the baby sucks immediately at the breast.

Before coming out the baby does not utter a cry, even if, during a difficult birth, its head sticks out but its whole body stays inside.

Those women in whom the purging of the discharges[432] starts prematurely have more difficulty in delivering the fetuses. If the purgations become less after the birth, and if only the first ones occur and do not last for up to forty days, the women get stronger and conceive more quickly.

The babies, when they are born, for forty days neither laugh nor cry while they are awake, though at night they sometimes do both; nor do most of them perceive it when they are being tickled; most of the time they sleep. But as it grows, it all the time changes to being more awake; and it is clear that it is dreaming, though it is only later on that it remembers what appears in the dreams.

In the other animals there is no difference between the bones, but all are completely formed; in babies, on the other hand, the bregma is thin, and solidifies later on. And while the other animals are born with teeth, babies start to grow teeth in the seventh month; they first grow the front teeth, some the upper ones first,

431. 586b6.
432. 586b33–35.

others the lower ones. And all the ones whose nurses' milk is hotter grow them more quickly.

7.11
Lactation

After the giving of birth and the purgations, milk is plentiful in women, and in some it flows not only at the nipples but at many places on the breast, and in some even in the armpits. And for some time afterward indurations remain, when liquid is not fully concocted and does not emerge, but accumulates; for the entire breast is so porous that if women swallow a hair in their drink, a pain occurs in their breasts (which they call "hair-sickness"[433]) until the hair either comes out spontaneously through squeezing or gets sucked out with the milk.

Women have milk until they have conceived again; then it stops and dries up alike both in the human beings and in the various live-bearing four-footed animals. While the milk is still coming out, the purgations of menses do not occur, for the most part, since cases have been observed of purgation while suckling. In general, the flow of liquid does not occur in several places at the same time—for example, in women with hemorrhoids the purgations are less. In some, the flow goes through the hips after being secreted from the loins but before reaching the uterus. Also, those who, when their purgations of menses do not occur, vomit blood are not at all harmed. **588^{a}1**

7.12
Convulsions in Babies

It is usual for most babies to be attacked by convulsions, and more so if they are well nourished and get milk that is both more abundant and[434] more coarse-grained and whose wet nurses are well fleshed. Harmful with view to this condition is wine—red wine more than white, and when unmixed with water—and most of the things that cause wind and constipation. (Most deaths occur before the seventh day; that is why they give them names then, because of trusting more in their preservation from that point on.) Also, they suffer more [from convulsions] during a full moon; and it is dangerous in all babies if the convulsions start from the back, especially as their age increases.[435]

BOOK 8

8.1
Animal Psychology

As regards the rest of the nature of the animals and their generation, then, this is the mode. As for their actions and lives, they differ in accord with their characters and their nourishment. For present in most of the other animals too are traces of the modes that have to do with the soul, the precise ones that in the case of the human beings exhibit more evident differences. For tameness and wildness, mild-manneredness and harshness, courage and cowardice, sorts of fear and of confidence, sorts of spirit and of unscrupulousness, and, with regard to thought, likenesses of comprehension, are present in many of them, as in the case of the parts we spoke about.[436] For some of these differ by the more and less in comparison to the human being, as the human being does in comparison to many of the animals (for some of these belong in the human being more, some in the other animals more), while others differ by analogy; for as in the human being there is craft knowledge, wisdom, and comprehension, so in some of the animals there is another natural capacity of a similar sort. This sort of thing is most evident if we look at the case of childhood; for in children, though one can see, as it were, traces and seeds of the states that will be present in them later on, yet their soul at this time is no different (one might almost say) from the soul of the
588[b]1 wild beasts, so that it is not at all unreasonable if the same ones, or much the same ones, or analogous ones belong in the other animals.

Nature changes in such small steps from the inanimate to the animate that, due to the continuity, we fail to notice the boundary between these and where what is intermediate between them lies. For first after things of the inanimate kind are things of the plant kind; and among these, one differs from another in seeming to share more in life; but the whole kind, in comparison to the other bodies, seems pretty much like something animate, though in comparison to the animals, like something inanimate.

The change from these to the animals is continuous, as was said previously.[437] For some of the ones in the sea one might raise a puzzle as to whether they are an animal or a plant; for they are attached, and, when separated, many of this sort pass away—for example, the pinnas are attached, and the razor fishes, when pulled up, are unable to live. In general, the entire hard-shelled-animal kind are like plants in comparison to the animals that move by walking.

As regards perceptions, some of these give no sign at all of any, others an indistinct one. The nature of the body of some of them is flesh-like—for example, the so-called sea squirts[438] and the anemone kind; as for the sponge, it is altogether like the plants.

436. 486[a]15–487[a]10.
437. 588[b]5.
438. 531[a]17–19.

It is always by a small difference that one after another makes evident that they already possess more of life and movement. It is the same way with the actions of their life. For plants—all the ones that come to be from seed—manifestly have no other work than to generate again another like themselves; likewise in certain animals too, one can grasp no other work beyond the generation of offspring. That is why actions of this sort are common to all, but as soon as perception is added, their lives differ both as regards mating, because of the pleasure, and as regards giving birth and the rearing of offspring. Like plants, then, some animals simply complete their own generation of offspring in accord with the seasons; others also take trouble about the nourishment of their offspring, but when this is complete, they separate and do nothing further communally with them; but those that have more comprehension and a share in memory live longer and in a more political way with their offspring. **589^{a}1**

One part of the life for these animals is concerned, then, with actions having to do with the production of offspring, while yet another part is concerned with nourishment; for it is with these two things that the serious actions and the life of all animals are in fact concerned. Their nourishments differ most in accord with the matter of which they are composed. For the growth of each one comes about in accord with nature from this matter. But what is in accord with nature is pleasant; and all pursue the pleasure that is in accord with nature.

8.2
Terrestrial and Aquatic Animals

But the animals have been divided[439] according to their places; for some animals are terrestrial and others are aquatic. But this difference is stated in two ways; for some are said to be terrestrial and others aquatic because the former take in air and the latter water; while others—not taking either in, but being, in an adequate manner, naturally constituted in relation to the blend of cooling in one or other of these two elements—are called "terrestrial" or "aquatic" not because they breathe [air] or take in water, but because[440] of getting their nourishment and spending their time in the one or the other. For many, though taking in air and giving birth on land, get their nourishment from places covered by water and spend most of their time in water. These are precisely the ones, it seems, that, alone among the animals, play a double game;[441] for one could class them both as terrestrial and as aquatic animals.

Among those that take in water, none—either as a walker or as a flyer—gets its nourishment[442] from the earth, though among the walkers that take in air many [get theirs from the water]. Some do so in such a way, indeed, that they are unable to

439. $487^{a}10$–$^{b}32$, *Juv.* $477^{b}23$–$478^{a}10$.
440. Reading τῷ δὲ.
441. Reading ὡς ἔοικεν ἐπαμφοτερίζουσι.
442. Reading οὐδὲν οὔτε πεζὸν οὔτε πτηνὸν τὴν τροφὴν.

live when separated from the nature of water—for example, the so-called sea turtles, crocodiles, hippopotamuses, seals, and some of the smaller animals such as the freshwater turtle and the frog kind; for all of these, if they do not breathe during certain times, suffocate. Also, they give birth and rear their offspring on dry land, or in some cases near dry land, but spend their time in the water.

But the most remarkable of the animals in this regard is the dolphin, and any other of this sort there is either among the aquatic animals or among the other cetaceans that has this mode of life—for example, the whale and all the others that have a pipe. For it is not easy to class these either as aquatic only or as terrestrial only, if one must class those that take in air as terrestrial and those that take in water as aquatic in nature. For they partake of both; for they take in seawater, and discharge it through their pipe, and take in air with their lung. For they have this part and breathe. That is why, when it is caught in nets, the dolphin suffocates quickly because of not being able to breathe. Also, out of the water it lives a long time, moaning and groaning, like the other animals that breathe; further, when it is sleeping, it holds its snout above the water in order to breathe.

But to assign the same things to both divisions is absurd, since they are contraries; rather, it seems that one must further define what is aquatic. For while some take in water and discharge it due to the same cause as those that breathe air, for purposes of cooling, others do it on account of the nourishment; for they must get this in water and must take in the water at the same time, and the ones taking it in must have an instrument to eject it with. Those, then, that use water analogously to breathing have gills, while those blooded animals that take it in for nourishment have a pipe.[443] It is the same way with both the soft-bodied and the soft-shelled animals; for these also take in water on account of the nourishment.

Those that are aquatic in the other way, because of their body's blend and their life, are all those that take in air but live in the water, {or all those that take in water and have gills, but travel onto dry land and get nourishment; only one of this sort has been seen at present, the so-called water newt; for this, though it does not have lungs but gills, is four-footed, because it is in fact naturally terrestrial}.[444] The nature of all these seems as if it has been distorted, just as some males become female-like and some females male-looking. For by exhibiting a difference in their small parts, animals appear to differ greatly in the nature of their whole body. This is clear in the case of castrated animals; for after a small part has been disabled the animal changes toward the female. So it is also clear that if, in the composition that the animal has to start with, some very tiny part changes in size, if it has the form of a starting-point, the animal becomes, in the one case, a female and, in the other, a male, and if it is wholly done away with, neither. So too to be terrestrial and aquatic in both of the ways results from the change that occurs in small parts. That is why it happens that

443. I.e., a blowhole.

444. This conflicts with 589ª22–24, and so may be a later addition.

some animals become terrestrial and others aquatic. Also, some do not play a double game, while others do, because they partake of something of the matter that is in their composition, when they are coming to be, that is of the sort that they get their nourishment from; for each animal likes what is in accord with its nature, as was said previously.[445]

Since the animals have been divided into the aquatic and terrestrial in three ways (by taking in air or water, by the blend of their bodies, and third by the sorts of their nourishment), their lives follow along in accord with these divisions; for some animals, [their classification] follows along in accord with the blend and the nourishment and in accord with taking in water or air, while [the classification of] others follows along in virtue of the blend and [what sustains] their lives alone.[446]

Among the hard-shelled animals, those that are unmoving are nourished by the fresh water (for it is filtered through the coarse-grained parts because it is finer-grained than the seawater that is being concocted), just as they also received their coming to be from it at the start.[447] That there is fresh water in the sea and that it can be filtered in this way is evident; for some people[448] have actually made a test of this; for if one fashions a thin wax vessel, ties a cord around it, and lowers it into the sea empty, in a day and a night it takes in a quantity of water, and this water is manifestly fresh.[449]

The anemones nourish themselves on any small fish that strikes against them. They have their mouth in the middle; this is most clear to perception in the large ones. They also have, like the shellfishes, a duct through which [the residue of] the nourishment is passed out. The duct itself is up above; for the anemone seems to be like the fleshy inner part of the shellfishes, and it uses the rock as a shell.

The limpets too, when they detach themselves, go to other places to nourish themselves. Among the mobile hard-shelled animals, some are animal-eating and nourish themselves on small fishes—for example, the purpura (for it is carnivorous, which is why it is caught by baits of that sort); the others also nourish themselves on the plants that grow in the sea. **$590^{b}1$**

The sea turtles not only feed on the small shellfishes (for they have the strongest mouths of all; for whatever a sea turtle gets hold of, whether a stone or something else, it gnaws off and shatters), but also emerge from the water and feed on grass. They suffer and die when they are on the surface and get dried out by the sun; for they cannot easily descend again [into the water].

It is the same way too with the soft-shelled animals; for they are also omnivorous; for they feed on stones, mud, seaweeds, and excrement—for example, the rock crabs—and they are carnivorous. The crayfishes overpower even the large fishes, and

a sort of reversal[450] happens to some of these animals; for the octopuses overpower the crayfishes, so that if the crayfishes perceive them nearby in the same net, they die of fear. And the crayfishes overpower the conger eels; for because of their roughness the conger eels do not slip away from them. But the conger eels eat the octopuses; for the octopuses, because of their smoothness, cannot deal with them. (The soft-bodied animals are all carnivorous.) The crayfishes feed on the small fishes that hunt beside their lairs; for they occur in the deep seas in the sorts of places that are rough and stony; for it is in such places that they also make their lairs. Whatever the crayfish gets hold of, it conveys it to its mouth with its bipartite claw, like the crabs. It walks, in accord with nature, toward its front, when it is not frightened, with its antennas laid down at the sides; but when it has been frightened, it flees backward and projects its antennas out far. The crayfishes fight each other like rams with their horns, raising their antennas and striking with them. They are often seen together with each other and collected together like a herd. That, then, is the way the soft-shelled animals live.

Among the soft-bodied animals, the calamaries and the cuttlefishes overpower even the large fishes. The octopuses gather shellfishes mostly, extract the fleshy parts and nourish themselves on these; that is also why the fishermen recognize their lairs by the shells. But what some people say, that the octopus eats itself, is false; but some of them do have their tentacles gnawed off by conger eels.

The fishes all nourish themselves on the embryos,[451] when the normal times for these arrive, but the rest of the nourishment they get is not the same for all. For some of them are carnivorous only—for example, the selachians, the conger eels, the channas, the tunas, the sea bass, the dentex, the bonitos, the sea perch, and the muraena. The red mullets nourish themselves on seaweeds, shellfishes, and mud, and are carnivorous;[452] the gray mullets do so on mud, the *daskillos* on mud and excrement, the parrot wrasse and the melanurus[453] on seaweeds, the saupe fish on excrement and seaweeds (but it also feeds on prasion[454] and is the only fish caught with a gourd[455]).

All fishes, except the mullet, eat each other, especially the conger eels. The gray mullet and the mullet are, generally speaking, the only fishes that are not carnivorous. A sign of this is that they have never been caught with anything of this sort in the stomach, and the bait used for them is not animal flesh but barley bread. Every mullet nourishes itself on seaweed and sand. The gray mullet, which some call the *chelôn*, stays near the shore, but the *peraias* does not; the *peraias* feeds on its own mucus, which is why it is always hungry. The gray mullets feed on the mud, which is why they are heavy and slimy; they eat no fish at all. Because they spend their time in the mud, they frequently rise again after diving in order to wash off the slime. Their

455. The gourd was used as a float with a line attached.

offspring are not eaten by any animal, which is why they occur in large numbers; but when grown, they are eaten by the other fishes and especially by the *acharnôs*. The most greedy and insatiable of all the fishes is the mullet, which is why its stomach is distended and, when it is not starved, is of poor quality. When it is frightened it hides its head, on the supposition that it is hiding its whole body.

The dentex is also carnivorous and eats the soft-bodied animals. Often both it and the channa throw out their stomachs[456] when pursuing the smaller fishes, because the stomachs of these fishes are next to their mouth, and they have no gullet.

Some fishes, then, as was said,[457] are carnivorous only—for example, the dolphin, the dentex, the gilthead, the selachian fishes, and the soft-bodied animals. Others, for the most part, feed on mud, seaweed, oyster-green, and so-called *kaulion*,[458] and plant material—for example, the *phukis*,[459] the goby, and the rock fishes; the *phukis*, though it does not touch other flesh, does eat that of the carids. Often, though, they also feed on each other, as was said,[460] that is, the large ones on the smaller ones. A sign of their being carnivorous is that they are caught with this sort of bait. The bonito, the tuna, and the bass are also mostly carnivorous, but also feed on seaweeds. The sargus feeds on the leavings of the red mullet, and when the red mullet has disturbed the mud (for it is able to dig) and gone away, the sargus descends and feeds, and prevents those weaker than itself from descending with it.[461]

It seems that the so-called parrot wrasse is the only fish to chew the cud like the four-footed animals.

In the case of the other fishes, they hunt the smaller ones that are right opposite their mouths in the direction that it is natural to swim in; but the selachians, the dolphins, and all the cetaceans catch them by turning their underneath parts up;[462] for their mouth is down below. That is also why the smaller fishes save themselves more readily; otherwise, it seems that there would be altogether few of them; for the dolphin's speed and capacity to eat seem wondrous.

Among the eels, a few, in certain places, nourish themselves both on mud and on foodstuffs, if someone throws them these, yet the majority do so on fresh water; and the eel farmers take care of this, seeing to it that it is as clean as possible, always flowing out and flowing in over flat stones; or else they have the eel tanks plastered. For the eels quickly suffocate if the water is not clean; for they have small gills. That is why, when people hunt for eels, they disturb the water; and in the river Strymon eels are caught at the rising of the Pleiades;[463] for then the water and mud are troubled

462. The dolphin does not in fact do this.
463. In early May.

by winds occurring from contrary directions; otherwise, it is advantageous to give eel-hunting a rest.

When they are dead, the eels do not float on the surface, nor are they carried upward, like the majority of the fishes; for they have small stomachs. A few have fat, but most do not. When they are taken out of the water, they live for five or six days, for a longer period if there are north winds, for a shorter one if there are south ones. Also, if they are moved in the summer from the pools to the eel tanks they die, but in winter they do not. Also, they do not withstand changes that are violent—for example, if those carrying them happen to dip them into cold water; for often they are killed en masse. They also suffocate if they are kept in a small quantity of water. The very same thing also happens in the case of the other fishes; for they suffocate if they are always in the same small quantity of water, just as the animals that breathe do if air is enclosed and small in quantity. Some eels live for seven or eight years.

River fishes too get their nourishment by eating each other and by eating plants, roots, and anything they get hold of in the mud. They feed more during the night, while in the day they retreat into the depths.

As regards the nourishment of the fishes, then, this is the mode.

8.3
The Birds

Among the birds, the crook-taloned ones are all carnivorous and cannot swallow
592b1 grain even if fed by hand—for example, all the eagle kinds, the kites, both hawks,[464] both the pigeon hawk and the sparrow hawk (these differ greatly in size from each other), and the buzzard. The buzzard is the size of a kite and is seen throughout the year. Further, the bearded vulture and the vulture; the bearded vulture's size is greater than the eagle's;[465] its color is ashen; of the vultures there are two forms, one small and more whitish, the other larger and more ashen.

Further, among the night birds, some are crook-taloned—for example, the night raven,[466] the small owl, and the eagle owl. The eagle owl is in appearance like the little owl, but in size is no smaller than an eagle. Further, the *eleos*, the *aigôlios*, and the little horned owl.[467] Of these, the *eleos* is larger than a cock, the *aigôlios* is much the same size, and both hunt the jays. The little horned owl is smaller than the little owl. All three of these are alike in appearance and all are carnivorous.

Some of the non-crook-taloned birds are also carnivorous—for example, the swallow.

464. Cf. 9.36.
465. Cf. 619a12–13.
466. The horned owl, *Strix otus* (597b21–23).
467. 9.28.

Others are larvae-eaters—for example, the chaffinch, the sparrow, the *batis*, the greenfinch,[468] and the titmouse.[469] There are three forms of titmice: the finch titmouse is the largest (for it is the size of a chaffinch); another is the mountain titmouse (because it spends its time in the mountains), which has a long tail; and the third is like these, but differs from them in size; for it is the smallest. Further, the beccafico, the black cap, the bullfinch, the robin, the *epilais*, the *oistros*, and the *turannos*, which is a little larger than a locust, has a crimson crest, and is otherwise a charming and graceful little bird. The *anthos*: this bird is the size of a chaffinch. The mountain finch: this one is like a chaffinch, and much the same size, but has blue on its neck; it spends its time in the mountains. Further, the king bird,[470] and the rook. These then and birds of this sort are wholly, or for the most part, larvae-eaters.

The following are thorn-eaters: the *akanthis*,[471] the *thraupis*, and the goldfinch. For all these feed on thorns, but never on larva or on any other animate thing; they sleep and feed in the same place.

Others are the *sknipe*-eaters; they live mostly by hunting *sknipes*[472]—for example, the greater and the lesser pie; some call these "woodpeckers"; they are like each other, and have a similar voice, except that the greater pie's is larger; they both feed by flying onto tree trunks. Further, the green woodpecker: the green woodpecker is the size of a turtledove and is entirely green in color; it is a vigorous pecker of wood, and feeds mostly on the tree trunks; it has a large voice. This bird occurs mostly around the Peloponnese. Another is called the "*sknipe*-picker"; it is as small as the *akanthullis*,[473] and ashen and speckled in color; its voice is small; it too is a pecker of wood.

There are others that live by eating fruit and herbage—for example, the wood pigeon, the common pigeon, the wine-colored pigeon, and the turtledove. The wood pigeon and the common pigeon are seen all the time, the turtledove[474] in summer; for in winter it vanishes; for it goes into hiding. The wine-colored pigeon is both seen and caught mostly in fall. In size the wine pigeon is larger than the common pigeon but smaller than the wood pigeon; the catching of it mostly occurs when it is gulping down water. They arrive in these places with their offspring. All the other birds that arrive in summer build their nests here; and most rear their offspring on live animals, except the pigeon-like ones.

Among (one might almost say) all the birds, some search for their nourishment on land, others live around rivers and lakes, others around the sea; all the web-footed ones spend most of their time on the water itself, those that are split-footed beside the water itself; among these, some nourish themselves on plants (those that are not

473. $616^{a}4$–6.
474. Cf. $597^{b}4$, $600^{a}20$–22, $613^{b}2$–3.

593b1 carnivorous). For example, those around lakes and rivers: the heron and the white heron; the latter is smaller than the former in size, and it has a beak that is flat and long. Further, the stork and the gull; the gull is ashen in color. Also, the *schoinilos*, the *kigklos*,[475] the *truggas*;[476] it is the largest of these smaller birds; for it is the size of a thrush. These birds all move their tails. Further, the *skalidris*; this bird is variegated, but overall ashen. Also, the halcyon kind lives near water. There are in fact two forms of these: one sings while settling in the reeds, the other is voiceless; it is larger; both have blue on the back. Also, the crocodile bird.[477]

Around the sea: both the halcyon and the *kêrulos*.[478] Also, the crows feed by taking animals that are washed up on the shore; for the crow is omnivorous. Further, the white gull, the *kepphos*,[479] the *aithuia*,[480] and the *charadrios*.[481]

Among the web-footed birds, heavier ones are around the rivers and lakes—for example, the swan, the duck, the *phalaris*, the grebe; further, the teal, which is like the duck but smaller in size, and the so-called raven;[482] it is like the stork in size, except that it has shorter legs; it is web-footed, a capable swimmer, and black in color; alone among birds of this sort, it settles in trees and builds its nest there. Further, the goose, the small gregarious goose, the Egyptian goose, the *aix*, and the *pênelops*.

The sea eagle spends its time around the sea and seeks prey in lakes.[483]

Many birds are also omnivorous. The crook-taloned ones take any other animal they can overpower, including birds; except that they do not eat members of their own kind, in the way that the fishes often take even their own.

The entire bird kind drinks little, while the crook-taloned ones do not drink at all,
594a1 except for a small kind and these only rarely. The kestrel is especially of this sort. The kite also drinks rarely, but has been seen drinking.

8.4
The Hard-Scaled Animals

The hard-scaled animals—for example, the lizard and the other four-footed ones, and the snakes—are omnivorous; for they are both carnivorous and eat herbage. The snakes are also the most gluttonous of the animals.

475. 615a22–24.
476. Reading ὁ τρύγγας.
477. As at 612a21; not the wren (also *trochilos*) as at 609b12, 615a17.
478. Perhaps a sort of halcyon.
479. 9.35. Perhaps the stormy petrel.
480. 542b17.
481. Perhaps the plover.
482. The cormorant.
483. Cf. 620a5–7.

These animals also drink little, and so do all the others that have their lung spongy; and all ones with little blood and the egg-laying animals have a spongy one. The snakes also lack self-control in regard to wine, which is why some people hunt even vipers by putting out wine in little pots in dry-stone walls; for they are caught when drunk.

The snakes are carnivorous, and whatever animal they catch, they suck dry and eject whole with their excrement. It is pretty much the same with the other animals like this—for example, the spiders; but the spiders suck out the juices outside, while the snakes do so in their stomach.

The snake takes from whatever is presented to it (for it eats small birds and beasts, and gulps down eggs), and, after taking it, the snake draws back until it is set in a straight line to its extremity, and then it draws itself in and contracts into a small space in such a way that, when it has stretched out, what it has gulped has gone down [into its stomach]. It does this because its gullet is thin and long. Both venom-spiders and snakes are capable of living a long time without food; this may be observed from the animals that the medicine-makers rear.

8.5
The Wild Sawtoothed Animals

Among the live-bearing four-footed animals, those that are wild and sawtoothed[484] are all carnivorous; except that the wolves, they say, eat a certain sort of earth when hungry, and are the only animals to do so. These animals do not touch herbage, but when they are ill, just like the dogs also do,[485] they eat it, vomit, and purge themselves.

Among the wolves themselves,[486] the ones hunting alone are more likely to eat human beings than those hunting in packs.

The animal that some people call the *glanos* and others the "hyena" is in size no smaller than a wolf, but has a mane like a horse, but with hair that is harder, denser, and extends along the whole spinal column. It plots against and hunts human beings, **$594^{b}1$** and it hunts dogs by making sounds like human beings vomiting;[487] also, it digs up graves because of its longing to eat this sort of flesh.

The bear is omnivorous. For it eats both fruit (climbing up into trees in virtue of the suppleness of its body) and legumes; it also eats honey (after breaking into the beehives), crabs, and ants, and is carnivorous. For because of its strength it attacks not only deer but also wild pigs (if it is able to fall upon them unawares), and bulls; for it advances toward the bull and, when it is in front of him, falls over on its back, and, when the bull tries to strike, it catches him around the horns with its front legs, and,

484. $501^{a}18–19$.
485. $612^{a}5–7$.
486. Retaining αὐτῶν.
487. Presumably the dogs are attracted by the prospect of having vomit to eat.

by biting his shoulder with its mouth, throws the bull down. It can walk for a short time upright on two legs. All the flesh it eats, it first lets putrefy.

The lion is carnivorous like all the other animals that are wild and sawtoothed. It deals violently with its meat, and gulps down much of it whole without cutting it up, and then does not eat for two or three days; for it is able to do this because it is overfull. It drinks little. It discharges residue rarely; for it passes it on the third day or whenever it happens to be, and it is hard and dry, like a dog's. It also discharges wind that is very acrid, and its urine has an odor, which is why, like the dogs, it sniffs at trees; for it urinates by lifting its leg like the dogs. It also produces a heavy odor in what it is eating by breathing on it; for when it is opened up its inside also releases a heavy vapor.

Some wild four-footed animals get their nourishment around lakes and rivers; but none does so around the sea, except the seal. Animals of this sort include the so-called *kastôr*,[488] the *satherion*, the *saturion*, the otter, and the so-called *latax*; it is broader than the otter, and its teeth are strong; for, coming out at night, it often cuts down the aspen around the river with its teeth. The otter also bites human beings and does not let them go, so they say, until it hears the bone crack. The *latax* has hard hair, and its appearance is intermediate between the hair of the seal and that of the deer.

8.6
Modes of Drinking; The Pigs

The sawtoothed animals drink by lapping; so also do some that are not sawtoothed—for example, the mice. But those with teeth that meet drink by suction—for example, the horses and the cows. The bear, though, drinks neither by suction nor by lapping but by gulping. Among the birds, all drink by suction, except that the long-necked birds at intervals raise their head; the *porphuriôn* alone does so by gulping.

The horned animals, both tame and wild, and all that are not sawtoothed, are grain-eaters and herbivores, unless very overcome by hunger, except the pig; for it is least of all a herbivore and a grain-eater. The pig, among all animals, is most a root-eater because its snout is naturally well adapted for doing this work;[489] among the animals, it has the strongest stomach for every sort of nourishment. It is also the quickest to increase in fatness in proportion to its size; for it fattens up in sixty days. The amount of the increase is something those who busy themselves about these matters come to know by weighing the pig when it is starving. Before being fattened, it is first starved for three days (pretty much all the other animals are also starved before being fattened). After three days, those fattening the pigs feed them well. The Thracians fatten them by giving them something to drink on the first day, then they

488. Probably the beaver.
489. *PA* 694^b13–14.

leave an interval of one day the first time, after that two, then three, then four, up to seven days. This animal is fattened on barley, millet, figs, acorns, wild pears, and cucumbers. But keeping still is what most fattens these, and other animals that have warm stomachs; and, in the case of pigs, wallowing in the mud too. They like to feed in groups of the same age. The pig fights even with the wolf. A sixth of its live **$595^{b}1$** weight goes into its hair, blood, and things of this sort. Sows and all other animals get thinner when they are suckling.

Of these matters, then, this is the mode.

8.7
The Cows

The cows eat both grain and herbage, but are fattened on the wind-producing vegetables, such as bitter vetches, bruised beans, bean stalks, and, in the case of older animals, if, having cut into their skin, one inflates them, and after that offers the nourishment; further, on barley, both simply as it is and winnowed, and on sweet foods, such as figs and raisins, and on wine and elm leaves. But, above all, they are fattened by sunny days and warm baths.[490]

The horns of young cows, when warmed with wax, easily go in whichever direction one pleases; they suffer less with their feet if one smears the horny parts with wax, oil, or pitch. When being moved, the herds suffer more from frost than from snow.

Cows grow larger when they remain unmated for several years; that is why in Epirus they keep the so-called Pyrrhic cows[491] unmated for nine years, calling them "apart from the bull," when they are growing. They say that these cows number around four hundred, are the private property of the kings, and are unable to live in any other region; and yet some people have tried this.

8.8
The Horses, Mules, and Asses

The horses, the mules, and the asses are grain-eaters and herbivores, but are fattened above all by their drink; for as the beasts of burden drink water, so they are too as regards the enjoyment they take in their nourishment, and where drinking displeases them least is where this is more fattening. Green pasture, when it is full of seed, makes them have smooth hair; but when it has hard awns, it is not good. The first cut of the Median grass[492] is bad, as is the grass anywhere that is supplied with foul-smelling water; for it scents the grass.

490. These help to concoct or digest the food.
491. $522^{b}23–25$.
492. $522^{b}26$.

The cows look for clean water to drink, while the horses are like the camels; the camel drinks with pleasure water that is turbid and coarse-grained; indeed, it does not **596ᵃ1** drink from rivers without having stirred them up. It is able to hold out for up to four days without drinking; then, after that, it drinks a large quantity.

8.9
The Elephants and Camels

The elephant[493] eats at most nine Macedonian medimni[494] of barley at one meal; but so large a quantity is dangerous. Normally it eats six or seven medimni, five medimni of hulled barely seeds, and five mareis of wine (a maris is six *cotyles*). An elephant has been observed to drink fourteen Macedonian metretae of water at one time, and eight more again that afternoon.

Most camels live for around thirty years, some much longer; for they even live for up to one hundred years. But the elephant, some people say, lives for around two hundred years, others say three hundred.

8.10
The Sheep and Goats

The sheep and the goats are herbivores, but the sheep get their pasturage by being persistent and staying in one place, while the goats change places quickly and touch only the tops of the plants. What most fattens the sheep is what it drinks, that is why in summer people give then salt every five days, a medimnus per one hundred animals; for this makes the flock healthier and fatter. Also, because of this they salt most of the food they offer—for example, they put a lot of salt in the bran (for when thirsty, they drink more) and in fall they sprinkle the gourd with salt; for this also increases the milk [they produce]. Also, if they are kept moving at midday, they drink more toward evening. Also, when they are ready to give birth, ewes fed with salt let down bigger udders.

One also fattens sheep on young olive shoots, wild olive, vetch, and bran of any sort; all fatten more when sprinkled with brine. These animals too[495] fatten more if they are first starved for three days. In fall, water from the north[496] is better for sheep than water from the south, and pastures that face west are advantageous; but travels and hardships make them thin.

493. 9.46.
494. An uncertain quantity. An Attic medimnus ≈ fifty-two liters.
495. 595ᵃ22–24.
496. Perhaps water facing into the north wind, or else rain driven by it.

In winter, the shepherds recognize the strong ewes by the fact that they have frost on them, while the other ones do not have it; for, because of their weakness, the ones that are not strong move around and throw it off. **$596^{b}1$**

The flesh of all the four-footed animals is worse in places where they graze on marshy ground than in places where they graze on more lofty ones.

The broad-tailed sheep winter better[497] than the long-tailed ones, and the short-wooled more than the shaggy; but the goats[498] actually winter badly. The sheep, in any case, are healthier than the goats, though the goats are stronger than the sheep.

The fleeces and the wool of sheep that have been eaten by wolves, and the clothes made from them, are much more infested with lice than the others.

8.11
The Insects

Among the insects, those that have teeth are omnivorous, while those that have only a tongue nourish themselves on liquids, sucking out juice with it from all quarters. Some of these are omnivorous (for they have a taste for all the juices)—for example, the flies; others are bloodsuckers—for example, the horsefly and the gadfly; and others live on the juices of plants and fruits. The bee is the only one that neither settles on anything putrefying nor takes any nourishment except what has a sweet taste. They take water for themselves with the greatest pleasure where it springs up pure.

———

The sorts of nourishment taken by the animal kinds, then, are the ones that have been stated.

8.12
Migration: Birds

The actions[499] of these animals are all concerned with mating and the production of offspring, with the easy means of providing nourishment, or are contrived with an eye to periods of cold and of heat and the changes of the seasons. For all animals have an innate perception of change as regards heat and cold, and just as among the human beings some change to living in their houses in winter, while others who control a large territory spend the summer in the cold parts and the winter in the warm ones, so it is too with those animals that are able to change their places.

497. Reading εὐχειμερώτεραι.
498. Reading αἶγες.
499. $589^{a}2$–5.

Some of them find protection in their own accustomed places, while others migrate: after the fall equinox, they flee from the Black Sea and the cold places to escape the approaching winter; after the spring one, they flee from the warm places to cold ones for fear of hot spells. Some make the change from nearby places, but others do so from (one might almost say) the furthest extremes, as the cranes do; for they move from the Scythian plains to the marshes above Egypt from which the Nile flows; this is also where the Pygmies live; for they are no myth, but there truly is a kind that is small, as was said, both of the people and their horses, and they live in holes. The pelicans also migrate; they fly from the river Strymon to the Ister and give birth there. They depart in a gathering, those in front waiting for those behind, because, when they have flown over the mountain, those in front are invisible to those behind.

The fishes are the same way: some move out of the Black Sea and back into the Black Sea; others move in winter from the deep sea toward the land, pursuing the heat, and, in summer, from inshore to the deep sea, fleeing the heat.

Also, the weak [kinds] of birds, in winter and times of frost, come down to the plains for the heat, but in summer go back to the mountains above because of the hot spells. It is always the weaker ones that are first to make the move at each excess—for example, the mackerels before the tunas, and the quails before the cranes; for the former move in Boedromion, the latter in Maemacterion.[500]

All are fatter when they move from the cold places than from the warm ones—for example, the quails are fatter in fall than in spring. The move from the cold places happens at the same time as the hot season finishes. Also, they have more of an impulse to mate in the spring season and when they move from the warm places.

Among the birds, the cranes, as was said previously,[501] migrate from the furthest extremes to the furthest extremes. They fly against the wind. But the story about the stone is false; for it is said that they contain a stone as ballast, which when they vomit it up is useful for testing gold.

Both the wood pigeons and the rock pigeons depart, and do not winter here. So also do the swallows and the turtledoves;[502] but the common pigeons remain here. Similarly, quails depart too, except for any turtledoves and quails that remain in sunny places. The wood pigeons and the turtledoves herd together, both when they arrive and again at the season for departure. When the quails have descended, if the weather is good or there is a north wind, they form couples and are quiet,[503] but if there is a south wind, they have difficulties because of not being flyers; for the wind is wet and heavy; this is also why hunters try to get them during south winds. In good weather they do not fly well because of their weight; for their body is large. That is why they cry when flying; for they are suffering. When they come to land

500. Around September, in the one case, October, in the other.
501. 597ᵃ4–6.
502. Cf. 593ᵃ17–18, 600ᵃ20–22, 613ᵇ2–3.
503. Reading ἠρεμοῦσιν.

from overseas, they do not have leaders; but when they depart from here, the *glottis* departs with them, together with the mother quail, the horned owl, and the *kuchramos*, which is precisely the one that also calls them in the night. When the hunters have heard its voice, they know that the quails are not remaining here. The mother quail is much the same as the marsh birds in shape, and the *glottis* has a tongue that it puts out a long way. The horned owl is similar to ordinary owls and has plumicorns by the ears; some people call it the "night raven." It is mischievous and an imitator, and, while imitating the dance [of one hunter], is caught by the second of the two hunters going around behind it, just like the ordinary owl.

In general, all the crook-taloned birds are short-necked, flat-tongued, and imitative; for the Indian bird, the parrot, which is said to be "human-tongued," is also of this sort; it becomes even more undisciplined after drinking wine.

The birds that live in herds include the crane, the swan, the pelican, and the small goose.

8.13
Going into Hiding: Fishes

Among the fishes, as was said previously,[504] some move toward the land from the deep sea, and to the deep sea from the land, fleeing the excesses of cold and heat. Those **598ª1** that occur inshore are better than those in the deep sea; for they have more and better food to feed on; for where the sun falls, the plants grow in greater abundance and are better and more tender, as in gardens. And the black shoreweed[505] grows near the land, while the other sort is like the wild plants. Further, the places in the sea that are inshore succeed in blending hot and cold well; that is also why, in fishes of this sort, the flesh is more firm in composition, while that of the deep-sea fishes is watery and flaccid.

The inshore fishes are the dentex, the black bream, the sea perch, the gilthead, the mullet, the red mullet, the wrasse, the weever fish, the *kalliônumos*,[506] the goby, and all the rock fishes. The deep-sea ones are the stingray, the selachians, the white conger eels, the channa, the erythrinus, and the *glaukos*. The sea bream, the scorpion fish, the black conger eels, the muraenas, and the cuckoo fish play a double game. And there are differences among these fishes also with respect to their places—for example, around Crete the gobies and the rock fishes all become fat. The tuna becomes good

504. $597^{a}13$–17.

505. Omitting the lacuna. A *this* is a sandbank at $537^{a}25$ and $548^{b}6$, but here seems to be a sort of marine plant.

506. Perhaps the stargazer, *Uranoscopus scaber*.

again after Arcturus;[507] for the gadfly[508] ceases in this season; for it is because of this it is worse in summer.

Many of the fishes also occur in sea-lagoons—for example, the saupe fish, the gilthead, the red mullet, and pretty much most of the others. The bonitos also occur there—for example, around Alopeconnesus; and in the Bistonis lake most of the fish kinds are present.

Many of the coly-mackerels do not enter the Black Sea, but summer in the Sea of Marmora, give birth there, and winter in the Aegean. The tunas, the young tunas, and the bonitos enter the Black Sea in spring, and summer there, and so do pretty much most of the fishes that go in shoals with the current and live in herds. Most fishes live in herds. And all the ones that live in herds have a leader. They all swim into the Black Sea for the nourishment; for the feeding is both more abundant and better because of the fresh water and the large savage fishes are fewer (for apart from the dolphin and the porpoise there is none in the Black Sea, and the dolphin is small; but immediately on leaving the Black Sea there are large ones). They swim in, in fact, both for the nourishment and for giving birth; for there are places suitable for giving birth, and the fresh and sweeter water nourishes the embryos. And when they have given birth and the offspring have grown, they swim out immediately after the Pleiades.[509] If the winter wind is a south wind, they swim out more slowly, if it is a north one, they do so more quickly, because the wind assists their movement. Also, the offspring caught then around Byzantium are small, because they have not spent much time in the Black Sea.

The others are clearly seen both swimming out and swimming in; the *trichias*[510] are the only fishes that are caught swimming in, but are not seen swimming out; in fact, when one is caught around Byzantium, the fishermen purge[511] their nets completely because it is not an ordinary thing for them to swim out. The cause is that these are the only fishes that swim up into the Ister, and then, where it divides, they swim down into the Adriatic.[512] A sign of this is that there the contrary happens; for they are not caught swimming into the Adriatic, but are caught swimming out.

The tunas swim in keeping to the right-hand shore, but swim out keeping to the left-hand one. Some say they do this because they see more sharply with the right eye, but by nature are not sharp-sighted.

The fish that go in shoals with the currents travel by day, but at night they rest and feed if there is no moon; but if there is one, they travel and do not rest. Some who live

507. Its morning rising in mid-September.
508. 557[a]27–28.
509. Probably its morning setting in early November.
510. 569[b]25.
511. To render them pure in the religious sense. Catching a *trichias* is taken as a potentially bad omen.
512. The Ister and the Adriatic were thought to connect.

around the sea say that when the winter solstice occurs, these fishes no longer move but stay at rest wherever they happen to have arrived, until the equinox.

The coly-mackerel are caught swimming in, but less often leaving. They are best in the Sea of Marmora before giving birth. The other fishes that go in shoals with the currents are caught more while leaving from the Black Sea and are best then. When they are swimming in, those caught nearest the Aegean are fattest, while the further up they are, the thinner they get. Often too, when a south wind resists the **599^{a}1** coly-mackerel and the mackerel as they swim out, one catches them further down more than around Byzantium.

This, then, is the mode in which the fishes make their migrations.

The same affection also occurs in the land animals in regard to going into hiding; for they have an impulse to go into hiding in winter and to quit their hiding place in the warmer season. The animals also go into hiding for aid against the excesses of either of the two seasons. In some cases, the whole kind goes into hiding; in others, some do, others do not. For the hard-shelled animals all go into hiding—for example, the ones in the sea: purpuras, trumpet-shells, and all of that kind. Going into hiding is more noticeable in the case of the detached animals (for they hide themselves, like the scallops, or they have an operculum on top of them, like the land snails), but in the undetached animals the change is invisible. They do not go into hiding in the same season, but rather the snails in winter, the purpuras and trumpet-shells at the Dog Star,[513] for around thirty days, and the scallops around the same time. And most of them also go into hiding in very cold spells and in very hot ones.

8.14
Going into Hiding: Insects

The insects pretty much all hide, except for any that live with human beings in houses, as well as those that die and do not live for more than a year. The others go into hiding in winter. Some go into hiding for a large number of days, others for the wintriest ones—for example, the bees; for these also go into hiding. A sign of this is that they are not seen to taste any of the nourishment set out for them; and if one does creep out, it appears transparent, and it is clear that there is nothing in its stomach. The bees are quiet from the setting of the Pleiades[514] until spring.

The animals go into hiding by hiding themselves in warm places and in places where they habitually sleep.

513. The morning rising in mid-July.
514. The morning setting in early November.

8.15
Going into Hiding: Blooded Animals and Fishes

Many of the blooded animals—for example, the hard-scaled ones, the snakes, the lizards, the geckos, and the river crocodiles—also go into hiding for the four wintriest months, and do not eat anything. The other snakes go into hiding in the earth, but
599ᵇ1 the vipers hide themselves under rocks.

Many of the fishes go into hiding too, most noticeably the *hippouros* and the sea crow in winter; for these are the only ones that are not caught anywhere except at certain fixed times that are always the same. Pretty much all the rest go into hiding.[515] The muraena, the sea perch, and the conger eel also go into hiding. The rock fishes form couples, males with females, when they go into hiding, just as for giving birth to offspring—for example, the wrasses, the *kottuphos*, and the perch. The tunas also go into hiding during winter in deep waters, become fattest after hiding, and start to be hunted from the rising of the Pleiades until the setting of Arcturus[516] at the latest. The rest of the time they stay quiet hiding. But some of these too, as well some other fishes that go into hiding, are caught during the time of going into hiding, since they move, if the place is warm and the weather is unexpectedly good; for they emerge from their lair for a little while to feed; they also do so at times of a full moon.

Many fishes are most pleasant tasting when in hiding.

The one-year-old tunas hide themselves in the mud; a sign of this is the fact that they are not caught, and also that they appear with a lot of mud on their back and with their fins pressed in. But in the season just mentioned,[517] they start moving and proceed toward land to mate and give birth, and they are caught pregnant. That is when they are believed to be in season; the fall and winter ones are believed to be inferior. At the same time too the males are seen to be full of seminal fluid. When the embryos they contain are small, these fish are difficult to catch, but when they are bigger, many are caught because of the gadfly.[518]

Some fishes go into hiding in the sand, others in the mud, with only their mouth projecting.

Most fishes go into hiding only in the winter, while the soft-shelled animals, the rock fishes, the rays, and the selachians do so only during the wintriest days; this is made clear by their not being caught when it is cold.

But some of the fishes go into hiding during the summer too—for example, the *glaukos*; for it goes into hiding in summer for around sixty days. The hake and the gilthead also go into hiding; and it seems to be a sign of the hake going into hiding
600ª1 for a very long time that it is caught at very long intervals.

515. Reading φωλεῖ.
516. Early May–late October.
517. The rising of the Pleiades in early May (599ᵇ10). Reading εἰρημένην.
518. 557ª27–28.

A sign of the fishes too going into hiding during the summer seems to be that catches are made at "the stars,"[519] and especially at the Dog Star; for at these times the sea is most stirred up. It is precisely in the Bosporus that this is well known; for the mud comes up to the surface and the fishes are carried up with it. They say too that often when the bottom of the sea is dragnetted more fishes are caught in the same net the second time than the first. And when there have been large storms, many [marine] animals appear that have previously not been seen at all or not often.

8.16
Going into Hiding: Birds

Many of the birds go into hiding too, and it is not the case, as some people think, that all migrate to warm places. On the contrary, some whose places of permanent residence are near places of this sort—for example, the kites and the swallows—depart to these; others that are further away from such places do not migrate but rather hide themselves. For many swallows have been seen in sheltering places altogether featherless, and kites have been seen flying out of such places when they first appear.

There is no distinction in going into hiding between the crook-taloned and straight-taloned birds; for the stork, the blackbird, the turtledove, and the lark go into hiding; in fact, the turtledove[520] is the most commonly assented to case of all; for no one (one might almost say) has been said to see a turtledove anywhere in winter. When it starts its going into hiding it is very fat, and though it molts during hiding, it nonetheless remains fat.

Among the wood pigeons, some go into hiding, and some do not go into hiding, but depart at the same time as the swallows. The thrush and the starling also go into hiding, and among the crook-taloned birds, the kite goes into hiding for a few days, also the owl.

8.17
Going into Hiding: The Four-Footed Animals

Among the live-bearing four-footed animals, both the porcupines and the bears go into hiding. That the wild bears go into hiding is evident, but whether due to the cold or due to some other cause is disputed. For around this time the males and the females become very fat, so that they cannot move easily. The females also give birth around this time, and go into hiding until it is time to bring out the cubs; this she does in spring, around the third month after the solstice. The bear goes into **$600^{b}1$**

519. $568^{a}18$.
520. Cf. $593^{a}17–18$, $597^{b}4$, $613^{b}2–3$.

hiding for at least around forty days; of these there are fourteen, they say, in which it does not move at all, but on most of the following ones, though it is still in hiding, it moves and wakes up. A pregnant bear has either never, or else very rarely, been caught. During this time it is evident that the bears eat nothing; for they do not emerge, and when they are caught, their stomach and intestines are seen to be empty. It is also said that because nothing goes into it, the intestine almost grows together, and because of this, when a bear first emerges, it eats arum in order to separate and dilate the intestine.

The dormouse too goes into hiding inside the trees themselves, and becomes very fat then; also, the white mouse from Pontus.[521]

Some of the animals that go into hiding also cast off their so-called old age;[522] this is the outermost skin and the sheath around the developing animals.[523] Among the terrestrial live-bearing animals, the cause of the bear's going into hiding is disputed, as was said previously.[524] Among the hard-scaled ones, though, pretty much most go into hiding, and those of them whose skin is soft and do not have a shell like that of the turtle (for both the land turtle and the freshwater turtle are among the hard-scaled ones) cast off their old age—for example, the gecko, the lizard, and above all the snakes; for they cast it off both in spring when they emerge and again in fall. The vipers also cast off their old age in spring and fall, and it is not the case, as some say, that this is the only kind of snake not to cast it off. When the snakes start to cast it off, it comes away first from the eyes in all cases, so that they seem to be becoming blind to those who do not understand the affection of casting off; after that, it comes off the head, which appears white in all snakes. The entire old age is stripped off in around a night and a day, starting from the head and ending at the tail. While the snake is casting it off, its inner layer becomes the outer; for it casts it off like fetuses
601ᵃ1 emerging from their chorions.

Those insects too that cast off their old age cast it off in the same way—for example, the cockroach, the *aspis*,[525] and the coleopterans—for example, the dung beetle. All cast it off after developing; for as with the chorion in those born to live-bearing animals so it is also with the sheath in those born to larvae-generating ones, alike in both the bees and the crickets. The cicadas, when they have emerged, settle on olive trees and reeds. They emerge when the sheath has broken open, leaving behind a little liquid, and not a long time afterward, they fly up and sing.

Among the marine animals, the crayfishes and the lobsters cast off their old age in spring and sometimes in fall after giving birth. Cases have been observed of crayfishes being caught in which the parts around the thorax are soft, because their shell has broken off, while the lower parts are hard, because it has not yet broken off there;

521. Perhaps the marmot.
522. 549ᵇ26.
523. 601ᵃ1.
524. 600ᵃ28–30.
525. Reading ἀσπὶς as at 487ᵇ5.

for they do not do their casting off in the same way as the snakes.[526] (The crayfishes go into hiding for around five months.) The crabs also cast off their old age, the soft-shelled ones by common consent, but they say that the hard-shelled ones do it too—for example, the *maia*.[527] When they are casting it off, the shell becomes altogether soft, and the crabs, at any rate, are hardly able to walk. Animals of this sort cast off not once but many times.

All the animals that go into hiding, both when they do so and how they do so, and further, which ones cast off their old age and when, have now been spoken about.

8.18
The Influence of Climate on the Birds

The animals do not all thrive in the same seasons, nor do they all do so equally in extreme weather conditions; further, states of health and sickness vary with the seasons in distinct ways in animals of distinct kinds, and, in general, are not the same for all.

Dry conditions are advantageous for the birds, both for their other health and for giving birth, not least for the wood pigeons, while rainy ones are so for the fishes, except for a certain few. And on contrary in each case, rainy years are disadvantageous for the birds (for, in general, it is not even advantageous for them to drink much), dry ones for the fishes. The crook-taloned birds, as was said previously,[528] generally speaking do not drink at all (but Hesiod[529] was ignorant of this; for in his poem narrating the siege of Ninus the eagle that presides over prophecy is drinking). The other birds drink, but are not big drinkers; nor, likewise, are any of the egg-laying animals that have a spongy lung.

Ailments in birds are noticeable in their plumage; for it is disturbed and does not have the exact same orderliness as when they are healthy.

8.19
The Influence of Climate on the Sea Fishes; Their Diseases

Most of the fish kind thrive more, as was said previously,[530] in the rainy years; for they not only have more abundant nourishment then, but also rainy weather is, in general, advantageous, as it is also to what grows from the earth; for garden vegetables, even

526. $600^{b}27–30$.
527. $525^{b}4$.
528. $593^{b}29–594^{a}1$.
529. There is no such passage in Hesiod. Some mss. read "Herodotus" in place of "Hesiod," others "Homer."
530. $601^{a}28–29$.

if irrigated, nonetheless benefit more from rain. The same happens to the reeds that grow in the marshes; for one might almost say that they do not grow at all unless rains occur. A sign of this is that most fishes migrate to the Black Sea in summer; for, because of the number of rivers, the water is sweeter, and the nourishment the rivers bring down plentiful. Further, many of the fishes even swim up the rivers and thrive in rivers and in lakes—for example, the bonito and the mullet. The gobies also become fat in rivers; and, in general, the regions that are well supplied with lakes have the best fishes. As for the rains themselves, summer rains are more advantageous for most fishes; also, when spring, summer, and fall have become rainy, but the winter is good. Generally speaking, when the season is good for the human beings, it turns out to be that most fishes thrive then too.

In cold places, on the other hand, they do not thrive. And the ones that suffer most in winters are those with a stone[531] in the head—for example, the *chromis*, the bass, the *skiaina*, the braize;[532] for because of the stone they become solidified due to the cold and are cast ashore.

Though rain is more advantageous for most fishes, for the mullet, the gray mullet, and the fish that some call the *marinos*, it is the contrary; for most of them are quickly blinded by heavy rains, if these are excessive. The gray mullets usually suffer this more in winters; for their eyes become white; when they are caught then, they are thin; and in the end are altogether destroyed. But it seems that it is not principally due to the heavy rain that they suffer this, but rather due to the cold; at any rate, many cases have been observed, in various places and especially in the willows around Nauplia in the Argolid, of blind fishes being caught after severe cold; many have been caught, in fact, that have white eyes. The gilthead also suffers in winter, and in summer the *acharnôs*, and they become thin. But for the crowfishes, in contrast to (one might almost say) all other fishes, dry years are more advantageous; in their case, though, it is because heat occurs more in dry ones.

Places are advantageous for each kind of fish for thriving. All those that are by nature inshore fishes or deep-sea fishes thrive in one or the other of these, while those that play a double game, do so in both; but there are also certain places special to each kind, in which they thrive. Generally speaking, places full of seaweed are advantageous; at any rate, among those fishes that feed in all sorts of places, those caught in the ones full of seaweed are fattest; for the seaweed-eaters are well provided with nourishment, and the flesh-eaters meet with more fishes.

North winds and south winds also make a difference; for the large fishes thrive more in north winds; and in summer, at the same location, more fishes are caught that are large and broad.[533]

531. The otolith.

532. *Pagrus pagrus*.

533. Alternatively (reading ἢ τῶν πλατέων and translating μακρὰ as "broad"): "for the long fishes thrive more in north winds; and in summer, at the same location, more long fishes are caught than broad ones."

The tunas and the swordfishes are driven mad by gadflies at around the rising of the Dog Star;[534] for at that time they both have beside their fins a sort of small larva that is called a "gadfly," which is like a scorpion, but the size of a spider; these produce such pain that sometimes the swordfish leaps out of the water no less high than the dolphin; that is also why they often fall onto ships. Among the fishes, the tunas most enjoy the warmth, and go toward the sand by the shore for the sake of warmth, and because they get hot, they come up to the surface. **$602^{b}1$**

Among the small fishes, their little ones survive due to being overlooked; for it is the larger ones that the large fishes pursue. Of the eggs and the seminal fluid most perish because of the sources of heat; for what they touch, they ruin all of.[535]

The fishes are mostly caught before sunrise and after sunset, and, in general, around the times of the sun's setting and rising; for these are the times said to be "ripe" for throws with the casting net, which is why fishermen take up their nets at that time. For the fishes are most deceived by their sight at these times; for they are quiet at night, and see better as the light increases.

No pestilential disease is seen to attack any of the fishes, such as often occurs in the human beings and, among the live-bearing four-footed animals, in the horses, the cattle, and certain others, both tame and wild; however, they certainly seem to get sick. Fishermen are given proof of this by some fishes being caught that are thin, sickly looking, and have changed color in among many of the same kind that are fat when caught.

As regards the sea fishes, then, this is the mode [of climatic influence].

8.20
Diseases of River and Lake Fishes; Influence of Climate

In the river and lake fishes, pestilential diseases do not occur either, but certain of them are attacked by illnesses special to themselves—for example, the sheatfish which, mostly around the time of the Dog Star, due to swimming near the surface, gets sunstroke, and also becomes stupefied by violent thunder. This also sometimes happens to the carp, but to a lesser degree. The sheatfishes, when struck by *drakôn*[536] in the willows, are also destroyed in large numbers. In the *baleros* and the *tilôn* an intestinal worm appears at the time of the Dog Star that causes them to rise to the surface and makes them weak; and when they have come to the surface, they are destroyed by the burning heat. The *chalkis* is attacked by a violent disease: lice occurring in large numbers under the gills destroy it. Among the other fishes, no disease of this sort occurs.

534. The morning rising in mid-July.
535. *GA* $753^{a}21–27$.
536. Identity uncertain. At $598^{a}11$ a *drakôn* is a weever fish; at $609^{a}4$ and $612^{a}30$ it is a land snake of some sort.

Fishes are killed by mullein;[537] which is why people hunt them by poisoning them with mullein in the rivers and lakes; the Phoenicians even poison those in the sea.
603ᵃ1 Some people also engage in two other sorts of fish hunts. For because they flee in winter from the deep water in rivers (for even otherwise the fresh water is cold),
5 people dig a trench to the river through the dry land; then they cover it with grass and stones, making a sort of lair[538] that has an exit from the river; when there is a frost, they catch the fishes from it with a wicker trap. Another sort of hunt is engaged in in summer and winter alike: making a dam in the middle of a river with sticks and stones, they leave out only so much as is needed for an opening; inserting a wicker
10 trap in this, they catch the fish by removing the surrounding stones.

Rainy years are advantageous for the other hard-shelled animals, but not for the purpuras. A sign of this is that if they are placed where a river discharges, when they have tasted the [fresh] water, they die the same day. The purpura, when it has been
15 caught, lives for around fifty days. They are nourished by each other; for a sort of seaweed and oyster-green develops on their shells afterward. The nourishment people throw to them, is "for the weighing scales," they say, to draw them down more. Droughts, though, are not advantageous for the other hard-shelled animals; for they
20 become smaller and worse, and the red scallops become more so then. In the straits of Pyrrha, at one time, the scallops disappeared, not only because of the instrument with which the fishermen hunted them and scraped them up, but also because of the droughts. And for the other hard-shelled animals too, rainy years are advantageous,
25 because the sea becomes sweeter. In the Black Sea, because of the cold, hard-shelled animals do not occur, nor in the rivers, except for a few of the bivalves; the univalves mostly solidify when it freezes.

30 As regards the aquatic animals, then, this is the mode [of climatic influence].

8.21
Diseases of Pigs

Among the four-footed animals, the pigs suffer from three diseases, one of which is called *bragchos*, in which mostly the parts around the jaws and windpipe become
603ᵇ1 inflamed.[539] But it can also occur in any random part of the body; for often the foot is attacked, and sometimes it is in the ear. The contiguous part also becomes putrescent immediately, until the putrescence reaches the lung; then the animal dies. The disease grows quickly, and the animal eats nothing, when the condition has started, even
5 ever so slightly. The pig-keepers treat it—when they perceive it while it is small in extent—in no other way than this: they cut out the whole of it.

537. Mullein (*plomos* or *phlomos*) is *verbascum sinuatum*.
538. Reading φωλεὸν.
539. Some of the symptoms are consistent with anthrax, others with foot-and-mouth disease.

There are two other diseases, both called *kraura*, one of which is a pain and heaviness in the head, and is the one that most are attacked by; the other is diarrhea. It seems to be incurable, while the former is relieved by applying wine to the nostrils and washing the nostrils with wine. But this one is also difficult to escape from; for it kills in two or three days. They mostly get *bragchos* when the summer brings figs and the pigs are fattest; it is relieved by giving the animal mulberries, by a bath in plenty of hot water, and if one bleeds it under the tongue.

Pigs with watery flesh get hailstone-like lumps[540] around the legs, neck, and shoulders; in these parts the hailstones occur in the greatest numbers. If the pig has few of them, the flesh is sweeter, but if it has many, it becomes very watery and insipid. Those suffering from hailstones are clear to perception; for not only do they have many of them under the tongue, but also if one plucks hairs from their bristly mane, they appear to be suffused with blood; further, those afflicted with hailstones are unable to keep their back feet quiet. They do not have hailstones while they are still only sucklings. [The pig-keepers] get rid of the hailstones by feedings with einkorn, which is also useful for nourishment.

The best thing for fattening and nourishing pigs is chickpeas and figs, but, in general, one must produce nourishment that is not simple but varied; for they enjoy changes in nourishment, just like the other animals. At the same time, they say, while one sort of nourishment produces wind, another flesh, and another fat, acorns alone, though eaten with pleasure, make the flesh watery; and, if they eat too many when pregnant, they miscarry, just as the sheep also do; for in the latter it is more noticeable that this happens because of the acorns. **604^{a}1**

The pig, though, is the only animal we know that suffers from hailstones.

8.22
Diseases of Dogs

Dogs suffer from three diseases, which are named "rabies," "dog-quinsy," and "foot-disease." Among these, rabies produces madness in a dog, and when it bites, all animals that have been bitten go mad, except the human being. This disease also kills the dogs.[541] Dog-quinsy also kills the dogs; and only a few escape from foot-disease. Rabies also attacks the camels. But elephants, they say, though they are untouched by other illnesses, are troubled by bouts of wind.

540. Actually tapeworm larvae.

541. Secluding καὶ ἄν τι δηχθῇ ὑπὸ λυττώσης πλὴν ἀνθρώπου ("and any animal bitten by a rabid dog, except the human being").

8.23
Diseases of Cows

The cows in herds get sick with two diseases, one called "foot-disease" and the other *kraura*. In foot-disease the feet swell, but the cows do not die or shed their hooves; they stand it better if the horny parts are smeared with hot pitch. When they have *kraura*, their breath becomes hot and thick; and what in the human beings is fever, in cows is *kraura*. A sign of the illness is that they droop their ears and are not able to eat. They die quickly, and when they are cut open the lung is seen to be putrescent.

8.24
Diseases of Horses

Among the horses, those at pasture are untouched by any illness other than foot-disease, but they suffer from this and sometimes shed their hooves; but when they shed them, they grow them again immediately; for the growing of the one hoof underneath occurs at the same time as the shedding of the other. A sign of the illness is that the right testicle twitches, or in the middle, a little below the nostrils, a sort of hollow develops that is wrinkled-looking.

Stabled horses suffer from many illnesses; for they are also attacked by *eileos*. A sign of the illness is that they draw up the back legs to the front legs and bring them close together, so that they almost come into collision. If it goes without food on the previous days and then goes mad, one relieves the pain by bleeding and by castration. Tetanus also attacks them; a sign of it is that the blood vessels, head, and neck are all tense, and the animal advances stiff-legged. Horses also develop abscesses. Another painful illness that attacks them is called *kritiasis*.[542] A sign of this illness is the palate becoming soft and the breath hot. These are incurable, unless they subside spontaneously.

There is also a disease called *nymphia*, in which the horse becomes possessed and looks down when someone plays the flute; when one mounts it, it bolts until one manages to get control of it;[543] but it always looks down, even when it goes mad. Also, a sign of this is that it lays its ears back toward its mane and then raises them again, stops, and breathes [with difficulty].

The following are also incurable: pain in the heart (a sign is a loose bowel and pain), displacement of the bladder (a sign of this is not being able to urinate, and the horse draws up its hooves and haunches), and if it closes its jaws on a *staphulinos*; this is the size of a *sphondulê*.[544]

542. Caused by eating too much barley.
543. The text of the final clause is uncertain.
544. Both seem to be sorts of beetles (542a10).

The bites of a shrew are dangerous, as they also are to other beasts of burden; for pustules are produced. The bite is more dangerous if the shrew is pregnant when it bites; for then the pustules burst, while otherwise they do not. When what some call a *chalkis* and others a *zignis* bites, it kills or produces intense pain; it is like the small lizards, but its color is like that of the blind snakes.[545] In general, those with experience say that pretty much all the illnesses that afflict the human being also afflict the horse and the sheep. By the drug, red sulfide of arsenic,[546] [illness] is dissipated both in the horse and in every beast of burden; it is given in water that is filtered.

A pregnant mare miscarries at the odor of a lamp being extinguished; this also happens to some pregnant women.

As regards the diseases of horses, then, this is their mode. **605^{a}1**

The so-called hippomanes grows on foals, as was said,[547] and the mares, as they are licking around and cleaning, nibble it off. But the additional stories about it are more likely fabricated by women and by those dealing in charms. But mares, by common consent, in fact eject the so-called *pôlion*[548] before the foal.

Horses recognize the voiced sounds of any horse they happened to have fought against just by hearing it. Horses like meadows and marshes; for they drink turbid water, and if it is clean, they stir it up with their hooves, then, after drinking, they bathe in it. For in fact the animal is, in general, bath-loving and water-loving; that is also why the nature of the hippopotamus[549] is composed as it is. But the cow is the contrary of the horse; for unless the water is clean, cold, and unmixed with anything, it is not willing to drink it.

8.25
Diseases of Asses

The asses suffer mostly from one disease, which is called *mêlis*. It occurs around the head first, and phlegm that is thick and red runs down the nostrils; if it goes down into the lung, it kills; but what occurs around the head is not fatal. This sort of animal is most sensitive to the cold; that is why asses do not occur around the Black Sea and Scythia.

545. $567^{b}25$–26.
546. Cf. $626^{a}7$.
547. $572^{a}21$, $577^{a}9$.
548. The membrane around the foal in the uterus.
549. Literally, "the horse of the river."

8.26
Diseases of Elephants

The elephants suffer from the flatulent diseases; that is why they are unable to emit either the liquid residue or that from the bowel. And if it eats earth, it becomes weakly, unless it does so continually; but if it does so continually, it is not harmed. It also gulps down stones sometimes. It is also attacked by diarrhea; when it is attacked, they treat it by giving it hot water to drink, and they dip the fodder in honey when giving it to the elephant to eat, and each of these puts a stop to it. When they are tired because of not having lain down to sleep, they are cured when their shoulders are rubbed with salt, olive oil, and hot water. When their shoulders are painful, they apply roasted pork, and this helps them. Some elephants drink olive oil, others do not; and if there happens to be some iron in an elephant's body, olive oil, when they drink it, expels the iron, so they say; to those who do not drink it they give a root they have boiled in the olive oil.

———

As regards the four-footed animals, then, this is the mode [of their diseases].

8.27
Diseases of Insects

Most of the insects thrive in the precise season in which they come to be, when the year is like the spring, wet and warm.

In the case of the bees, small beasts come to be in the hives that damage the combs. One is a little larva that spins a cobweb and damages the combs (it is called a *klêros*,[550] though some call it a *puraustês*; within the comb it gives birth to a sort of little spider that is like itself, and produces disease in the hive); another beast is like the moth that flies around a lamp; this one gives birth to something that is covered in fine down, and is not stung by the bees but flees only when fumigated. Caterpillars also appear in hives,[551] which the bees do not defend themselves against.

Bees most become diseased when the tree has blossoms that suffer from mildew, and in drought years.

All insects die if smeared with olive oil, and do so most quickly, if one anoints their head and exposes it to the sun.

550. $626^{b}17–19$.

551. Omitting ἃς καλοῦσι τερηδόνας ("which they call a *terêdôn*").

8.28
The Effects of Place on Animal Kinds

The animals also differ in accord with their places; for just as in certain places certain animals do not occur at all, so in certain places they occur, but are smaller or shorter-lived, and do not thrive. And sometimes the difference in such things is found in nearby places—for example, in neighboring places in Miletus, the cicadas[552] occur in one but not in the other, while in Cephalonia a river separates a part where the cicadas occur from a part where they do not occur. In Pordoselene a road separates the side on which the weasel occurs from the side on which it does not occur. In Boeotia the moles occur in large numbers around Orchomenus but in the neighboring Lebadia they are not, and if one takes them there, they are not willing even to dig. In Ithaca, hares—if **606^{a}1** one takes them there and releases them—cannot live, but are seen dead by the sea, turned in precisely the direction from which they came. In Sicily the horseman-ants[553] do not occur, and in Cyrene, the croaking frogs previously were not. In all Libya, there is neither wild pig, nor deer, nor wild goat. In India, as Ctesias (who is not really trustworthy) says, there is neither tame nor wild pig, but the blooded animals and the hard-scaled ones are all large. In the Black Sea neither the soft-bodied nor the hard-shelled animals occur, except for a few in certain places; but in the Red Sea all the hard-shelled animals are exceedingly large.

In Syria the sheep have tails that are a cubit in breadth; the goats have ears that are a span and a palm long, and in some the ears meet down below, near the ground; and the cows, like the camels, have humps on their shoulders. In Lycia the goats are shorn like the sheep in other places. In Libya the horned animals have horns right at birth, and not the males only, as Homer says,[554] but the others too. In the Black Sea region near Scythia, it is the contrary: they are born hornless.

In Egypt, though the other animals—for example, the cows and the sheep—are larger than in Greece, some are smaller—for example, the dogs, the wolves, the hares, the foxes, the ravens, and the hawks; and some are much the same size—for example, the crows and the goats. The cause is attributable to the nourishment, because it is plentiful for some, scarce for others—for example, for the wolves and the hawks (for there is little for the carnivores, for the little birds are scarce), and for the hares and all the non-carnivores, because neither nuts nor fruits last long. **606^{b}1**

In many places, though, the climatic blend is also a cause—for example, in Illyria, Thrace, and Epirus, the asses are small, while in Scythia, and in Celtic territory, they do not occur at all; for these animals cannot stand the cold.[555]

552. 556^{a}21–25.
553. Perhaps a sort of large flying ant.
554. *Odyssey* 4.85.
555. 605^{a}20–21.

In Arabia lizards occur that are over a cubit long, and mice that are much larger than field mice, with front legs that are a span long and back legs that are up to the first joint of the fingers in length.

In Libya, the size of the snakes is immense, so it is said; for some sailors say that they saw there the bones of many cows, which—as it became clear to them—had been eaten by snakes; for as they were putting out to sea, these quickly pursued their triremes, and plunged some of them into the water, when they overturned their trireme.

Further, the lions occur more in Europe[556] (that is, in the place in Europe that lies between the rivers Achelous and Nessus); the leopards, on the other hand, occur in Asia but not in Europe.

In general, the wild beasts are wilder in Asia, but all those in Europe are more courageous, though those in Libya are the most multiform; in fact it said in a proverb that "Libya always bears something new."[557] For because of the lack of rain, it seems that animals have sexual intercourse when they meet at the watering-places, even though they are not of the same kind, and they bring offspring to birth, if their pregnancies are the same, and if their sizes are not far from each other's; they become milder toward each other because of their need for drinking water. And, in fact, contrary to the animals of other places, they also need to drink more in winter than in summer; for because sources of water do not usually occur in summer, they are unaccustomed to drinking then. As for the mice [there],[558] when they drink, they die.

Other animals also come to be from the sexual intercourse of animals that are not of the same kind, as in Cyrene the wolves have sexual intercourse with the dogs and generate offspring; and from the fox and the dog, the Laconian hounds[559] are born. They also say that from the tiger and the dog, the Indian hounds are born[560]—not immediately, but from their third intercourse; for the first one born is savage, they say. They take the female dogs to deserted places and tie them up; and many are eaten, if the wild beast does not happen to be ready for mating.

8.29
The Effects of Place on the Lives of the Animals

Places also produce differences in the characters of animals—for example, mountainous and harsh places produce characters different from those in level and soft places; for even their appearances are more savage and more aggressive, like the pigs on Mount Athos; for the males do not even stand the females of the lower regions.

556. Reading Εὐρώπῃ.
557. *GA* 746ᵇ7–8.
558. Cf. 595ᵃ7–8.
559. Cf. 574ᵃ16–17, 608ᵃ27–28.
560. *GA* 746ᵃ34–35.

Also, with regard to the bites of the wild beasts, the difference between the regions is great—for example, around Pharos and other places the scorpions are not dangerous, but in other places, especially in Scythia, they are numerous, large, become dangerous, and kill any human being or other beast they strike, even pigs (which are least sensitive to the bites of other animals); and among these, they especially kill the black ones; the pigs that have been struck die more quickly if they go into water.

The bites of the snakes also differ a lot. For the asp occurs in Libya, which is the snake from which they make the putrefacient, and besides is incurable. A certain little snake also occurs in silphium,[561] for which the remedy is said to be a sort of stone they get from the tomb of one of the ancient kings, dip into wine, and drink.

In certain places in Italy the bites of the geckos are also deadly. But the bites of all the venomous animals are more dangerous if one happens to have eaten another—for example, a viper that has eaten a scorpion. But to most of them[562] human spittle is inimical. There is a small snake, which some call "sacred," that the very large snakes avoid; it becomes at most a cubit in length, and looks hairy; what it bites, immediately putrefies around the bite. There is also a small snake in India that is the only one for which they do not have a remedy.

8.30
The Effects of Pregnancy

The animals differ as to good condition or the contrary also in connection with pregnancy. For the hard-shelled animals—for example, the scallops, all the oyster-like animals, and the soft-shelled animals, for example, the crayfishes—are best when pregnant. Pregnancy is said of the hard-shelled animals too; even though, while the soft-shelled animals are seen mating and giving birth, none of these ever is. The soft-bodied animals are also best when pregnant—for example, the calamaries, the cuttlefishes, and the octopuses. **$607^{b}1$**

The fishes are pretty much all good when starting to be pregnant, but as pregnancy advances, some are and some are not. The *mainis*[563] is good when pregnant; the female's shape is rounder, that of the male longer and broader; the start of the female's pregnancy coincides with the male's having a dark and variegated color, and its being worst to eat. They are called "goats" by some people around this time.

The ones they call *kottuphos*, the wrasses, and the carid[564] also change color with the seasons, just like some of the birds; for in spring they become dark, then after spring they become light again. *The phukis* also changes color; for the rest of the time it is white, but in spring variegated; it is the only one of the sea fishes that builds

561. A plant whose juice was used in food and medicine.
562. Probably the venomous animals, but possibly their bites.
563. $570^{b}26$.
564. Reading καρὶς.

nests, as they say, and lays eggs in the nest. The *mainis* also changes [color], as was said,[565] and the picarel, and from a lighter color they change back again in summer and become dark; the change is most noticeable around the fins and gills.

The sea crow is also best when pregnant, like the *mainis*. But the mullet, the bass, and the soft-scaled fishes[566] are pretty much all of poor quality when pregnant. A few are the same whether pregnant or not—for example, the *glaukos*. Old fishes too are of poor quality; in fact, the tunas, when old, are of poor quality even for pickling; for much of their flesh wastes away. The same also happens in the case of the other fishes. The old ones are clear to perception from the size and hardness of the scales. An old tuna was once caught that weighed fifteen talents, and the dimension of its tail was five[567] cubits and a span.

The river and lake fishes become best when, after the discharge of the embryo and the seminal fluid, they have become fattened. Some are good when pregnant—for example, the *saperdis*; others are of poor quality—for example, the sheatfish. Though in the case of all the other fishes the males are better than the females, the female sheatfish is better than the male. In the eels too, those they call "females," are better; they call them "female," though they are not, but [only] differ in appearance.[568]

BOOK 9

9.1
Animal Psychology; War among the Animals

The characters of the animals that are more indistinct and shorter-lived are less clear to our perception, while those of the longer-lived ones are more clear. For they are seen to have a certain natural capacity corresponding to each of the affections of the soul: practical wisdom and foolishness, courage and cowardice, mild-manneredness and harshness, and the other states of this sort. Some animals share at the same time in some learning and teaching, some from each other, some from human beings, namely, all the ones that partake of hearing, not only the ones that hear sounds, but those that also perceive distinctly the differences between signs.

In all the kinds in which there are the male and the female, nature has distinguished the character of the females from that of the males in pretty much the same way. But the distinction is most evident in the case of the human beings, the animals having magnitude, and the live-bearing four-footed animals. For the character of the females is softer, quicker to be tamed, lets [human] hands approach, and is better

565. 607b12–13.
566. Reading λεπιδωτοὶ.
567. Reading πέντε.
568. Cf. 538a2–13.

at learning—for example, the female Laconian hounds are in fact naturally cleverer than the males. The kind of hounds in Molossia is no different for purposes of hunting from those in other places, but for following along with sheep it is superior in virtue of its size and its courage in facing wild beasts. And the ones that come from both kinds—from the ones in Molossia and the ones in Laconia—are superior in courage and love of labor.

All females are less spirited than the males, except the bear and the leopard; the female of these seems to be more courageous. But, in the other kinds, the females are softer, more malicious, less simple, more impetuous, and more thoughtful about the nourishment of the offspring, while the males, on the contrary, are more spirited, more savage, simpler, and less treacherous. **$608^{b}1$**

There are traces of these characters in (one might almost say) all animals, but they are more evident in those that have more of a character, and especially so in the human being; for this one has the most complete nature,[569] so that these states too are more evident in these. That is why a woman takes pity more than a man does, is more given to tears, and further, more envious, more nursing of grievances, more fond of abusing people, and more inclined to come to blows. The female is also more spiritless and despondent than the male, more shameless, more of a liar, readier to deceive, and has a longer memory; further, she is less sleepy, more timid, and, in general, less inclined to move than the males, and needs less nourishment.

On the other hand, the male, as was said,[570] is more ready to help and more courageous than the female, since even among the soft-bodied animals, when the cuttlefish has been struck by a trident, the male helps the female, while the female flees when the male is struck.

There is a war against each other among all the animals that occupy the same places and live on the same things; for if nourishment is scarce, even those of the same kind fight against each other; thus even the seals, they say, that live around the same place make war, male against male, female against female, until one kills or drives out the other; and the pups all do the same thing.

Further, all are at war with the carnivores, and these with the others; for they get their nourishment from animals. (It is also from this that the prophets get their dissociations and associations, positing as dissociates those that are at war with each other and as associates those that are at peace with each other.) But if there was no shortage of nourishment, it is probable that those that are now afraid of human beings and are savage would behave tamely, both toward human beings, and in the same way toward each other. This is made clear by the way animals are taken care of in Egypt; for because nourishment is taken for granted and is not in doubt, even the most savage animals live with each other; for they become tame because of these

569. *GA* $733^{a}32–^{b}16$.
570. Implied at $608^{b}3–4$.

benefits— for example, in some places the crocodile kind has become tame toward
609ᵃ1 the priest because their nourishment is taken care of. The same thing is seen to occur around the other countries too, and in their individual parts.

The eagle and the *drakôn*[571] are at war; for the eagle nourishes itself on snakes. Also, the tracker[572] and the venom-spider; for the tracker hunts the venom-spiders. Among the birds, the *poikilis*, the larks, the woodpecker, and the *chlôreus*; for they eat each other's eggs. And the crow and the owl; for at midday, because the owl does not see sharply during the day, the crow steals and eats its eggs, while the owl does the same during the night; and so, the one is stronger during the day, the other during the night. Also, the owl and the *orchilos* are at war; for it too eats the owl's eggs. During the day, the other little birds too fly around the owl (which is called "admiring" it), and fly at it and pluck out its feathers; that is why bird-catchers hunt all sorts of little birds by means of it. And the so-called old man[573] is at war with the weasel and the crow; for they eat her eggs and chicks.

Also, the turtledove and the *purallis*; for they feed and live in the same place. Also, the green woodpecker and the *libuos*. And the kite and the raven; for the kite steals whatever the raven has hold of, because of being stronger with his claws and in flight, so that their nourishment makes them enemies too. Further, those that live from the sea are also at war with each other—for example, the *brenthos*,[574] the gull, and the *harpê*.[575] And the buzzard, the toad, and the snake; for the buzzard eats them. Also, the turtledove and the *chlôreus*; for the *chlôreus* kills the turtledove. Also, the crow kills the so-called *tupanos*. The *aigôlios* and the other crook-taloned birds eat the *kalaris*; hence the war between them. There is also war between the gecko and the spider; for the gecko eats the spiders. And between the horse[576] and the heron; for it eats the heron's eggs and chicks. And between *aigithos* and ass there is war because, when the ass is nearby, it scratches its sores on the thorns; and because of this, and if it brays, it causes the eggs to fall out and the chicks; for they fall out [of the nest] because they are frightened; and the bird, because of this injury, flies at the ass and pecks at its sores.

609ᵇ1 The wolf is at war with the ass, the bull, and the fox; for being carnivorous, it attacks the cows, the asses, and the fox. Also, the fox and the *kirkos*[577] due to the same cause; for being crook-taloned and carnivorous, the *kirkos* attacks it and produces sores by striking it. Also, the raven is at war with the bull and the ass, because it flies at them, strikes them, and pecks at their eyes. The eagle and the heron are also at war; for being crook-taloned, the eagle attacks it and the heron dies while defending itself.

571. 602ᵇ25.
572. 552ᵇ26–30.
573. 615ᵃ17–20.
574. Perhaps the same as the *brenthos* mentioned at 615ᵃ16.
575. 610ᵃ11, 617ᵃ10.
576. Reading ἵππῳ.
577. 9.36.

Also, the merlin is at war with the vulture, the *krex*[578] with the *eleos*,[579] blackbird, and oriole (which some storytellers say was produced from a funeral pyre); for the *krex* injures both them and their offspring. Also, the nuthatch and the wren[580] are at war with the eagle; for the nuthatch breaks the eagle's eggs, and the eagle—both because of this and because it is carnivorous—is at war with all. And the *anthos*[581] is as war with the horse; for the horse drives it out of the pasture (for the *anthos* feeds on grass and, since it has a film over its eyes, is not sharp-sighted); for it imitates the horse's voice and frightens him by flying at him, and so he drives it out; but when he catches it, he kills it. (The *anthos* dwells beside a river and marshes, it has a beautiful color, and it lives well.) The ass is at war with the gecko; for the latter sleeps in his manger, and prevents him from eating by creeping into his nostrils.

There are three kinds of herons,[582] the gray, the white, and the so-called starry. Of these, the gray has difficulty in being mated and in mating. For it screams and releases blood, so they say, from its eyes while mating, and lays poorly and painfully. It is at war with those that injure it, with the eagle (which seizes it), the fox (which destroys it at night), and the lark (which steal its eggs).

The snake is at war with the weasel and the pig: with the weasel[583] when they are both in the same house; for they live on the same things; and the pig eats the snakes. Also, the merlin is at war with the fox; for it strikes it, plucks at it, and kills its offspring; for it is crook-taloned. But the raven and the fox are friends with each other; for the raven is at war with the merlin; that is why it aids the fox when it is being struck. Also, the vulture and the merlin are at war with each other; for both are crook-taloned. And the vulture even fights with the eagle. The swan does too; and the swan often prevails. The swans are also the most likely of all birds to eat each other. **610^{a}1**

Among the wild beasts, some are always at war with each other; others, like human beings, on occasion.

The ass and the *akanthis*[584] are at war; for the *akanthis* live on thorn bushes, and the ass eats the thorns when they are tender. Also, the *anthos*, the *akanthis*, and the *aigithos*; and it is said that the blood of the *aigithos* and the *anthos* do not mix with each other.

The crow and the heron are friends, and the *schoiniôn*[585] and the lark, and the *laedos* and the green woodpecker; for the green woodpecker dwells beside a river and thickets, the *laedos* in rocks and mountains, and they like the place where they dwell.

578. 616^{b}19–21. Perhaps the corncrake or the black-winged silt.
579. 592^{b}10–15.
580. 615^{a}17.
581. 592^{b}25.

583. Often kept as a pet.
584. 592^{b}30.
585. Perhaps the same as the *schoinilos* (593^{b}4).

Also, the *piphigx*, *harpê*,[586] and kite are friends, and fox and snake (for both live in holes), and blackbird and turtledove.

But the lion and the *thôs*[587] are at war with each other; for being carnivorous, they live on the same things. Elephants also fight fiercely with each other, and strike each other with their tusks; the defeated one is very much enslaved and does not dare to resist the victor's voice. The elephants differ from one another in courage to a wondrous degree. The Indians in fact use females just like males as war-elephants; however, the females are smaller and much less courageous. The elephant knocks down walls by striking its large tusks against them, and palm trees with his forehead, until it has bent them over, and then, by trampling on them with its feet, stretches them out on the ground. The hunt for elephants is as follows: the hunters pursue them mounted on elephants that are tame and courageous, and when they have caught one, they order those tame ones to strike it, until they have exhausted it; then the elephant-driver leaps onto it and directs it with his metal goad. After this it quickly becomes tame and obeys. While the elephant-driver is mounted, all are tame; but when he has dismounted, some are, others are not; but they bind the front legs of those that go wild, in order to calm them down. The hunt is both for those already large and for calves.

The friendships and the wars between these wild beasts, then, happen because of their nourishment and their mode of life.

9.2
War and Friendship among the Sea Fishes

610b1 Among the fishes some herd together with each other and are friends, while those that do not herd together are at war. Some herd together when pregnant, some when they are giving birth. In general, the fishes that herd together are the following: the tunas, the *mainis*, the gobies, the *boax*, the horse mackerels, the sea crows, the dentex, the red mullets, the *sphuraina*, the *anthias*, the *eleginos*, the *atherinos*, the *sarginos*, the garfishes, the calamaries, the rainbow wrasse, the young tunas,[588] the mackerel, and the colymackerels. Among these, some not only herd together but form couples too; the rest, though they all form couples, only form herds on some occasions, as was said,[589] some when pregnant, some also when they have given birth.

The bass and the mullet, although being the worst of enemies, herd together on certain occasions; for often not only those of the same kind herd together, but also those whose fodder is the same or much the same, if it is abundant.

586. 609a24, 617a10.
587. 507b17.
588. 571a11.
589. 601b2–3.

The mullets and the conger eels often live with their tail removed as far as the outlet for the residue; that of the mullet is eaten by the bass, that of the conger eel by the muraena.

There is war between the stronger and the weaker [fishes]; for the stronger eat them.

So much, then, for the sea fishes.

9.3
The Goats and the Sheep

The characters of the animals, as was said previously,[590] differ with respect to cowardice, mild-manneredness, courage, tameness, understanding, and foolishness. For the character of sheep, so it is said, is simple and foolish; for of all the four-footed animals it is the worst: it wanders into deserted places with nothing in view, and often in wintry weather goes out from inside, and when sheep are caught in a snowstorm, they are unwilling to leave unless moved by the shepherd; instead, they perish while remaining, unless the shepherds bring males; then they follow along.

As for the goats, when one pulls the tip of one female goat's beard (which is like hair), all the other female goats stand as if stupefied looking at her.

Sheep are colder than goats to sleep among; for the goats chew the cud more and come toward human beings; and goats are more sensitive to the cold than sheep.

Shepherds teach the sheep to run together when there is a noise; for if one is caught in a thunderstorm and does not run with the others, it miscarries if it happens to be pregnant; that is why if there is a noise, they run together into the house out of habit. The sheep and the goats lie gathered together in family groups. When the sun turns more quickly,[591] the shepherds say that the goats do not lie face to face, but back to back.

9.4
The Cows and the Horses

The cows too graze with their companions in herds, and if one wanders away, the others follow; that is why the cowherds, if they do not find a certain one, immediately search for all of them. {Even the bulls are destroyed by wild beasts, when they have left the herd and wandered away.}[592]

Among the horses that graze together, when a mare has died, the others rear her foals between them. And, in general, the horse kind seems to be by nature affectionate

590. $608^{a}13$–21.

591. The meaning is unclear but seems to refer to the earlier setting of the sun in winter.

592. Transposed from $611^{a}2$–3.

to the young. A sign of this is that often the barren mares take the mothers' foals and are the ones that show them affection, but because they have no milk, cause their death.

9.5
The Deer

Among the wild four-footed animals, the deer does not seem to be the least practically wise, because she gives birth beside roads (for the wild beasts do not approach because of the human beings) and, after giving birth, she first eats the chorion. Also, they run for the seseli[593] and eat it before returning to the offspring. Further, she leads the offspring to her lair, accustoming them to the place where they should take refuge; this is a precipitous rock, with one point of entry, which it where, they say, the deer then stands to defend herself.

Further, the male, when it has become fat (and it does become very fat in the fruit season[594]) does not make itself evident anywhere but goes off somewhere, because its fatness makes it easy to be caught. They also shed their horns in rugged places that are difficult to find; hence the proverb "where the deer shed their horns"; for having thrown away their weapons, they guard themselves from being seen. It is said that no one has yet seen the left horn; for the deer is said to hide it because it has some sort of medicinal property.

The deer do not grow horns in their first year except for a sort of starting-point as a sign of them; this it short and hairy. In their second year, they grow horns for the first time, straight like tent pegs; that is why people call these "peg-horns." In the third year, they grow them divided in two, and in the fourth year, rougher;[595] and in this way always increasing up to six years. After that, they always grow them the same
611[b]1 ones, so that one can no longer know their age by the horns, although people know the old ones mostly by two signs; for some have no teeth, others few, and they no longer grow the "defenders." The ones called "defenders" are the forward-pointing tips of the growing horns, with which they defend themselves; the old ones do not have these, instead the growth of their horns is straight upward. They shed their horns every year; they shed them around the month of Thargelion.[596] When they have shed them, they hide themselves during the day, as was said;[597] they hide in thickets to avoid the flies. During this time, they feed at night, until their horns have grown out. They grow in a sort of skin at first, and become hairy; but when they have grown, the

593. A medicinal herb (perhaps *Tordylium officinale*) used to treat prenatal and postnatal disorders.
594. 579[a]6.
595. Probably τρικρανῆ ("three-tipped") or the like should be read in place of τραχύτερον.
596. May.
597. 611[a]25–27.

deer sun themselves, in order to concoct and dry out the horn. When it is no longer painful to rub the horns on trees, they leave these places because they feel confident, since they have a means of defending themselves. And cases have been observed of an *achainês*[598] deer that was caught with a lot of green ivy growing on its horns, implying that the horns were tender when the ivy was implanted, as if in green wood.

When the deer have been bitten by a venom-spider, or something of this sort, they collect marjoram and eat it; this is believed also to be good for a human being to take in a drink, though it is distasteful.

The female deer, when they have given birth, immediately eat the chorion, and it is not possible to get hold of it; for they grasp it before it has fallen to the ground; it is believed to be a remedy.

The deer, when hunted, are caught by pipe playing and singing, and making them lie down due to the pleasure. There are two hunters: one sings or pipes in the open; the other shoots from behind, when the former indicates the opportune moment. If the deer happens to have its ears upright, it hears sharply and it is not possible to catch it unawares; but if it happens to have them laid back, it is possible.

9.6
Practical Wisdom in Animals

When the bears flee, they push their cubs forward and pick them up and carry them; and when they are being overtaken, they jump up into trees. And when they have come from their lair [after going into hiding], they first eat arum, as was said previously,[599] and chew sticks as if cutting teeth.

612^{a}1 Many of the other four-footed animals also do things to aid themselves in a practically wise way; thus in Crete, they say, that when wild goats are struck by arrows they look for dittany; this is believed to be effective in expelling arrows in the body. Also, when something pains dogs, they make themselves vomit by eating a certain herb.[600] And when the panther has eaten the poison, panther-bane,[601] it looks for human excrement; for this aids it. (This poison also kills lions.) That is why in fact the huntsmen hang the excrement in a container from some tree, in order that the beast not wander far away; for jumping up hoping to get hold of it, the panther dies. They also say that the panther, observing that the other animals like her odor, hunts them by concealing itself; for they come near; and in this way it catches even the deer.

The Egyptian ichneumon, when it sees the snake called the "asp," does not attack it until it has called on other ones to help. They plaster themselves with mud against

598. $506^{a}24$.
599. $600^{b}10$–12.
600. $594^{a}28$–29.
601. Probably aconite.

its blows and bites; for having first drenching themselves in water, they roll around in the earth.

When the crocodiles yawn, the crocodile birds fly in and clean their teeth, and so these get their nourishment, while the crocodile, perceiving that it is being benefited, does not harm them; and when it wishes them to leave, it moves its neck, in order not to crush them with its teeth.

When the turtle has eaten a viper, it eats marjoram after it; this has actually been seen. And once, when someone had seen a turtle doing this several times, and when it had plucked up some marjoram, going back again to the viper, he stripped the leaves off the marjoram; as a result of this, the turtle died. When the weasel fights a snake, it also eats rue; for its odor is inimical to snakes.

When the *drakôn*[602] eats fruit, it sucks the juice of *pikris*,[603] and has been seen doing this. When the dogs have worms, they eat the standing wheat. The storks and the other birds, when they have a wound from fighting, apply marjoram to it.

Many have seen even the cricket, when fighting with snakes, seize the snakes' neck.
612[b]1 The weasel too seems to overpower birds in a practically wise way; for it tears them by the throat as wolves do sheep. It also fights especially with mouse-eating snakes, because it too hunts the same animal.

As regards perception in hedgehogs, it has been observed in many places that, when north and south winds change places, the ones that live in the ground move their holes, while those that live in people's houses change [their places in relation to the] walls, so that a person in Byzantium, they say, gained a certain reputation for making a prediction based on observing the hedgehog doing these things.

The marten is around the size of the small dogs of Melite, and in its hairiness, its appearance, its white stomach, and the mischievousness of its character, it is like the weasel. Also, it becomes very tame, but does mischief to beehives; for it enjoys the honey. It is a bird-eater like the cats. Its sex organ, as was said,[604] is bony; that of the male is believed to be a remedy for strangury; they administer it by grating it up.

9.7
Practical Wisdom in Birds

In general, one may observe in the lives of the other animals many imitations of the life of human beings; and more so in the smaller ones than in the larger ones, one may see an exactness of thought—for example, in the first place, in the case of the birds, the nest-building of the swallows;[605] for in the mixing of straw with mud, it

602. 602[b]25.
603. Perhaps prickly goldenfleece (*Urospermum picroeides*) or prickly oxtongue (*Helminthia sepioides*).
604. 500[b]23–25.
605. *Ph*. 199[a]26.

keeps the same order.[606] It weaves together mud with the bits of straw; and if it is at a loss for mud, it drenches itself and rolls its feather in the dust. Further, it builds the nest in just the way the human beings do, in first putting the hard materials underneath and making the size of the nest commensurable with its own. As regards the nourishment of the offspring, both parents labor at it; they give some to each observing by a sort of intimate familiarity the one that has had it, so that it does not get it twice. Also, at first they themselves throw out the excrement [of the offspring], but when these have grown, they teach the chicks to turn around and emit it outside.

As regards the pigeons, there are other things supporting an observation of the same sort; for they are neither willing to form a couple with more than one partner, nor do they quit the partnership before becoming a widower or a widow. Further, as regards the pains of giving birth, the care of the male for the female and his sharing in her distress are extraordinary; and if she shows cowardice at entering the nest because of the birth, he strikes her and compels her to go in. When the chicks have **613^{a}1** appeared, he gives thought to suitable nourishment and, having masticated it,[607] spits it into the open mouth of the chicks, preparing it beforehand for their nourishment. When he is about to eject all of them from the nest, the male mates [with the female].

For the most part, this is the way pigeons are mutually affectionate, but sometimes even the females that have male partners are mated by others. The pigeon is a pugnacious animal, and the pigeons give each other trouble, and steal into each other's nests, although rarely; for they are less pugnacious when further away, but beside the nest, they fight to the end.

It seems to be a special affection of common pigeons, wood pigeons, and turtledoves not to lift their head when drinking if they have not drunk enough.

The turtledove and the wood pigeon each keeps the same male and does not submit to another; both the male and the female brood on the eggs. It is not easy to distinguish the female and the male except by their internal parts. The wood pigeons live a long time; for in fact twenty-five- and thirty-year-old ones have been seen, and even some forty-year-old ones.[608] When they are older, their claws grow; but those who rear pigeons cut them. No other infirmities are noticeable in old age.

Also, the turtledoves and the common pigeons that have been blinded by those who rear them as decoys live as long as eight years. As for the partridges, they live for around fifteen years. The wood pigeons and the turtledoves always nest in the same places. In general, males are longer-lived than females, but in the case of these birds, some say that the males die before the females, basing their proof on the decoys nurtured in the house. They also say that the male sparrows live for only a year, producing as a sign the fact that in spring they are not seen with the black around the beard from the outset, but acquire it later, suggesting that none of the previous

606. I.e., as human beings do when they make bricks this way.
607. Reading φροντίζει τῆς ἁρμοττούσης τροφῆς ἧς διαμασησάμενος.
608. 563^{a}1–2.

birds has survived. And they say that the female sparrows are longer-lived; for they are caught in with the younger birds and are distinguishable by the parts around the
613ᵇ1 beak being hard.

The turtledoves spend summer in the wintry places,[609] while the chaffinches spend
5 summer in the warm places and winter in the cold ones.

9.8
The Quails and the Partridges

The heavy birds do not build nests for themselves[610] (for it is not advantageous for them, since they are not flyers)—for example, the quails, the partridges, and the other birds of this sort; but when they have made a rolling place on level ground (for they do not lay eggs in any other place), and screened it with thorns and sticks as a defense
10 against the hawks and the eagles, they lay them and brood on them there. Then, as soon as they are hatched, they lead out the chicks, because they are unable to provide nourishment for them by flying. Both the quails and the partridges, like the chickens,
15 bring the chicks under them when they are resting. And they do not lay and brood in the same place, in order that no one discover the place by their sitting there too long. When someone chances upon a nest of young birds, and tries to catch them, the partridge rolls at the feet of the hunter, so as to seem easy to catch, and attracts him toward herself, so that it seems to him that he is about to catch her, until all the
20 chicks have scattered; after that she flies up and calls them back again.

The partridge lays not less than ten eggs, often sixteen. And, as was said,[611] the bird has a bad character and is cunning. In spring, by means of singing and fighting, they are separated out of the herd in couples with the females, each male with the female
25 he has got. And because they are lecherous, to prevent the female from brooding,[612] the males roll the eggs around and shatter them if they find them. But the female, contriving to counter this, lays after running away, and often, because of her readiness to lay, deposits them at random; if the male is near, so as to save the clutch of
30 eggs, she does not go near them. And if she is seen by a person, then just as she does with the chicks, she leads him away from the eggs, by appearing before the person's feet, until she has led him away.

When the female, having run away, broods on the eggs, the males join together in
614ª1 screaming and fighting; they call these "widowers." The one who has been defeated in the battle follows the victor and is mounted only by him. And if he is overpowered by a second male or any other, he is mounted by one that overpowers him in secret.[613]

609. Cf. 593ª17–18, 597ᵇ4, 600ª20–22.
610. 558ᵇ31.
611. Reference unclear.
612. Cf. 564ª20–23.
613. Presumably from the first victor.

This does not occur at all times, but in a particular season of the year; and it is the same way with the quails. Sometimes this happens with the cocks too; for in the temples, where they are presented as offerings without the females, they all with good reason mount the new arrival. Also, among the partridges, the tame males mount, peck, and are wantonly aggressive toward the wild males.

The leader of the wild partridges presses forward against the hunting partridge[614] and sings in answer to him, as when fighting. When this one has been caught in the nets, another comes forward in turn, and sings in answer in the same way. If the hunting one is a male, that is what they do; if it is a female that is hunting and singing, and the leader sings in answer to her, the others gather around and strike him, and chase him away from the female, because he is approaching her and not them. Because of this he often approaches her in silence, in order that no other male, hearing his voice, starts fighting with him. Sometimes, those with experience say, when approaching the female, the male keeps her quiet, in order that the males not hear and he not be compelled to fight against them.

The partridge not only sings, but also emits a scream and other voiced sounds. Often too, when brooding, the female stands up, when she has perceived the male turning toward the hunting female, and sings in answer and stays where she is, in order to be mounted by him and to tear him away from the hunting female. The partridges and the quails are so intensely excited about mating that they throw themselves on the hunters[615] and often settle on their heads.

As regards the mating and hunting of the partridges, then, and as regards their cunning character, these are the sorts of things that happen.

The quails and partridges nest on the ground, as was said,[616] and so do some of the other birds that are flyers. Further, among birds of this sort, the lark, the woodcock, and the quail settle not on a tree but on the ground.

9.9
The Woodpeckers

The woodpecker does not settle on the ground. It pecks at trees in order to make the larvae and *sknipes*[617] come out. For when they have come out, it collects them with its **$614^{b}1$** tongue; it has a broad and large one. Also, it moves by walking on the trees quickly in every mode, even upside down, like the geckos. It has claws that are naturally better than those of the jackdaws for security when settling in trees; for it walks by sticking them in.

614. A live bird used as a decoy.
615. Probably the hunting quails.
616. $613^{b}6$–12.
617. $593^{a}3$.

Among the woodpeckers, there is one kind that is smaller than the blackbird, which has small reddish markings; another kind is larger than a blackbird; and the third kind of these is not much smaller than a female chicken. It nests in trees, as was said,[618] and, among other trees, especially in olive trees. It feeds on the ants and larvae that come from trees. In hunting for larvae it hollows out trees with such vehemence, they say, that the trees fall down. Also, one that was being tamed once inserted an almond into a cleft in a piece of wood, in order that by being fitted there it would not escape his blow; on the third blow, he split it and ate the soft part.

9.10
The Cranes and the Pelicans

Many examples of practical wisdom also seem to occur among the cranes; for they migrate a long way and fly to the heights in order to see into the distance, and if they see clouds and bad weather, they fly down and rest quietly. Further, they have both a leader and signalers in the outermost positions that whistle, so that their voiced sound is heard. When they settle, while the others sleep with their head under their wing, on one foot and then on the other, the leader keeps watch with his head uncovered, and when he perceives something, he signals it with a cry.

The pelicans that occur on rivers gulp down the large smooth mussels; and when they have concocted them in the place before the stomach, they vomit them up, so that while the mussels are open, they can extract the flesh and eat it.

9.11
Bird Nests

The dwellings of the wild birds are devised both for their lives and for the preservation of their offspring. Some of them are kind to their offspring and take care of them, others are the contrary; some are good at devising things for life, others not good at devising. Some build their dwellings in ravines (*charadra*), others[619] in clefts and rocks—for example, the so-called *charadrios*.[620] The *charadrios* is base in both color and voice; it appears at night but shuns the day.

The hawk too nests in precipitous rocks. Although it is carnivorous, it does not eat the heart of the birds it overpowers; some have observed this both in the case of the quail and in the case of the thrush, and others in other cases. Further, they change their way of hunting; for they do not seize [their prey] in the same way in summer.

618. Perhaps thought to be implied by 614a34–35.
619. Reading οἱ δὲ.
620. 593b15.

It is said of the vulture[621] by some people that no one has seen either its chick or its nest. It is because of this, indeed, that Herodotus, the father of Bryson the sophist, said that the vulture comes from some other lofty land, citing as proof both this and the fact that many suddenly appear, and it is not clear to anyone from where. But the cause of this is that it gives birth in inaccessible rocks, and the bird is not native to many places either. It lays one egg, or at most two.

Some birds dwell on mountains or in the woods—for example, the hoopoe and the *brenthos*;[622] the latter bird lives well and is a singer. The wren[623] dwells in thickets and holes. It is difficult to catch, is a skulker, and has a weak character; but it lives well and is crafty. It is called the "old man" and the "king"; which is why, they say, the eagle is at war with it.

9.12
Aquatic Birds

Some birds spend their life near the sea—for example, the *kigklos*.[624] The *kigklos* is cunning in character and hard to catch, but when caught, it is very easily tamed. It also happens to be deformed; for it lacks control of its back parts.[625]

Also living near the sea, rivers, and lakes are all the web-footed birds; for nature itself seeks what is suitable. Many of the split-footed birds too spend their life near waters and marshes—for example, the *anthos* beside rivers; it has a beautiful color and lives well. The *katarraktês* lives near the sea, and when it dives into the depths, it stays for no less a time than it takes someone to walk a plethron; the bird is smaller than a hawk.

The swans are also among the web-footed birds, and they spend their lives near lakes and marshes; they live well, are good natured, kind to their offspring, and age well. If an eagle starts a fight, they defend themselves and prevail, but they do not start a fight themselves. They are singers, and they sing most at the time of their death; indeed, they also fly out to sea, and people sailing by Libya once came upon large numbers of them on the sea singing in a mournful voice and saw some of them dying. **$615^{b}1$**

The *kumindis* is seldom seen; for it dwells in the mountains. It is black, the size of the hawk called the "wood pigeon killer,"[626] and in appearance long and thin. The

621. $563^{a}5$–12.
622. $609^{a}23$.
623. $609^{b}12$.
624. $593^{b}6$.
625. I.e., it is a wagtail and/or (perhaps) lecherous.
626. $620^{a}18$.

Ionians call it *kumindis*; it is the one Homer mentions in the *Iliad*,[627] saying that "gods call it *chalkis*, but men *kumindis*."

The *hubris*, some people say, is the same bird as the *pôgx*.[628] It does not appear during the day because it does not see sharply, but at night it hunts like the eagles. And these birds fight against the eagle so violently that both are often caught alive by shepherds. The *hubris* lays two eggs, and it too[629] nests in rocks and caves. Cranes also fight against each other so violently that they too are caught while fighting; for they keep it up. The crane lays two eggs.

9.13
Other Birds

The jay changes its voiced sounds most often; for it emits a different one every day, one might almost say; it lays around nine eggs and builds its nests in trees from hair and wool; and when the acorns are starting to come to an end, it hides a supply of them.

As regards the storks, it is repeated over and over by some people[630] that they are nourished in return by their offspring. Some say that the bee-eaters do this same thing too and are nourished in return by their offspring, not only in old age, but also as soon as the offspring are able; and the father and the mother remain in the nest. The appearance of the bird's feathers is yellow on the underparts; the upperparts, like those of the halcyon, are dark blue; the tips of the wings are red. In fall, it lays around six or seven eggs in overhanging banks that are soft; it burrows in up to four cubits.

The bird called the "greenfinch" (because its underparts are [greenish] yellow) is as
616ᵃ1 big as the lark; it lays four or five eggs. It builds its nest from comfrey, which it pulls up by the roots, and carpets it with hair and wool. Both the blackbird and the jay do the same thing and make the inside of the nest from these materials.

The nest of the *akanthullis* is built in a craft-like way; for it is plaited together like a ball of flax, and has a small entry.

People who live in those places say that there is also a cinnamon bird that carries what is called "cinnamon" from some place or other, and whose nest is built from it. It nests in high trees and in the young branches of the trees. They say that the native inhabitants, by attaching a lead weight to their arrows and shooting at them, cause the nests to fall down, and in this way collect the cinnamon from the debris.

627. 14.291.
628. 617ᵃ9.
629. Like the eagle.
630. E.g., Aristophanes, *Birds* 1355.

9.14
The Halcyon

The halcyon[631] is not much larger than a sparrow. Its color is dark blue, green, and light purple; the entire body, the wings, and the parts around the neck have these in a mixed way, not each of the colors separately; its beak is greenish yellow, long, and thin. Such, then, is its appearance. Its nest is very like sea balls—so-called *alosachnê*[632]—except in color; their color is reddish, and their shape is much the same as that of the long-necked gourds. Their size is bigger than that of the biggest sponges; indeed, there are both larger and smaller ones. They are covered with a roof and have an extensive solid part and hollow part. Even when being cut with a sharp knife, they are not quickly cut through, but when one is being cut at the same time as being shattered with one's hands, it quickly shatters into pieces like the *alosachnê*. The nest's mouth is narrow, enough for a small entrance, so that even if the nest is overturned, the sea does not come in. The hollow parts are much the same as those of the sponges. One might raise a puzzle as to what the halcyon makes its nest from; but it seems most likely that it is from the spines of the garfish; for it lives by eating fish. It also goes up rivers. It lays around five eggs at most. It gives birth throughout life, starting at four months.

9.15
The Hoopoe and Others

The hoopoe mostly builds its nest from human excrement.[633] It changes its appearance in summer and winter, like most of the other wild birds. **$616^{b}1$**

The titmouse lays the most eggs, so they say. But some say that the so-called blackcap in fact lays most (after the Libyan sparrow, at least); for seventeen eggs have been seen; however, it in fact lays more than twenty. It always lays an odd number, so they say. This bird too nests in trees; it feeds on larvae. A special affection of this bird and of the nightingale in comparison to other birds is not having a sharp point to their tongue.

The *aigithos* lives well and has many offspring, but is lame of foot.

The oriole is good at learning and clever at satisfying life's needs, but is a poor flyer and has an ugly color.

631. $542^{b}4$–17.
632. Literally, "sea-foam." Perhaps a zoophyte of some sort.
633. Cf. $559^{a}8$–11.

9.16
Two Other Unidentified Birds

The *elea* lives as well as any other bird, and in summer settles in shady place facing the wind, but in winter in a sunny and sheltered place in the reeds near marshes. It is small in size, but has a good voice.

The so-called *gnaphalos* has a good voice, a beautiful color, is clever at satisfying life's needs, and is graceful in form. It is believed to be a foreign bird; for it is rarely seen in places that are not properly its own.

9.17
Other Birds

The *krex*[634] is pugnacious in character; in thinking it is clever at satisfying life's needs, but is otherwise an ill-fated bird.[635]

The so-called nuthatch is pugnacious in character; in thinking it is quick, orderly, and clever at satisfying life's needs; it is said to be a sorcerer because it knows many things; it is prolific and is kind to its offspring; it lives by pecking wood.

The *aigôlios*[636] feeds at night and rarely appears during the day; and it too[637] dwells in rocks and caves; for it lacks courage,[638] but in thinking it is clever at satisfying life's needs and good at devising things.

There is a small bird called the *kerthios*; this one is daring in character, dwells in trees, and is an eater of woodworms; as for thinking, it lives well and has a clear voice.

The *akanthis*[639] lives badly and has a bad color; it does, however, have a sweet voice.

9.18
The Herons

Among the herons, the gray one, as was said,[640] mates with difficulty, but it is good at devising things, carries meals back to the nest, hunts well, and works during the day. Its color, however, is poor and its stomach always wet.[641] Of the remaining two

634. 609[b]8–11.
635. Perhaps also a bird of ill-omen.
636. 563[a]31.
637. Like the hubris and eagle (615[b]15–16).
638. The text is uncertain.
639. 593[a]1–3, 610[a]6–8.
640. 609[b]23.
641. *PA* 674[b]30–34.

(for there are three kinds of them), the white one has a beautiful color and mates **617ª1**
unharmed; it nests and lays well in trees; it feeds in marshes, lakes, plains, and meadows. The starry heron, the one called the "hesitater," is said in stories to have been 5
born of slaves in ancient times; in keeping with its name, it is the laziest of them. The herons, then, live in this way.

The so-called *pôugx* has a special affection in comparison to other birds; for among all the birds, it is most given to pecking out the eyes. It is at war with the *harpê*;[642] for it has a similar mode of life. 10

9.19
The Blackbirds

Of the blackbirds there are two kinds: one is black and occurs everywhere, the other entirely white, equal in size to the former, its voice much the same. It occurs on Mount Cyllene in Arcadia, but nowhere else. Similar to the black blackbird is the *laios*,[643] in size a little smaller; it spends its time on the rocks and roof tiles; it does not 15
have a red beak like that of the blackbird.

9.20
The Thrushes

Of the thrushes, there are three forms. One is the mistle thrush. It eats nothing but mistletoe and pine resin; its size is that of the jay. Another is the *trichas*. It has a sharp call; its size is that of the blackbird. Another, which some call the *ilias*, is the smallest 20
of these and less variegated.

9.21
The Bluebird

There is a rock bird whose name is the "bluebird." This bird occurs mostly on Nisyros and spends its time in the rocks. Its size is less than that of the blackbird, but a 25
little larger than that of the chaffinch. It is big-footed and climbs up the rocks. It is entirely blue. It has a beak that is thin and long, and short legs, very like those of the woodpecker.

642. 609ª24, 610ª11.
643. Perhaps the blue thrush.

9.22
The Oriole and the Malakokraneus

The oriole is entirely yellow. This bird is not seen in winter; it becomes especially seen around the summer solstice; it departs when Arcturus is rising. Its size is that of the turtledove.

The *malakokraneus*[644] always settles in the same spot and is caught there. As for its form, its head is large and cartilaginous, and it is a little smaller than the thrush; its beak is strong, small, and round; in color it is entirely ashen; it is fleet of foot but a bad flyer. It is mostly caught by the owl.

9.23
Other Birds

There is also the *pardalos*. This bird lives in herds, for the most part, and it is not possible to see one by itself. Its color is entirely ashen, its size much the same as those just mentioned; it is fleet of foot and not a bad flyer; its voice is loud and not low-pitched.

The *kolluriôn* eats the same things as the blackbird; its size is also the same as the previous ones. It is caught mostly in winter; but all these birds are seen in all seasons.

Further, there are the birds that are accustomed to living mostly in cities, the raven and the crow; for they too are seen in all seasons, and do not change their places or go into hiding.

9.24
The Jackdaws

Of the jackdaws there are three forms. One is the chough; it is as large as the crow and red-beaked. Another is the so-called wolf. Further, the small one, the joker. There is also another kind of the jackdaws around Lydia and Phrygia that is web-footed.[645]

9.25
The Larks

Of the larks there are two kinds. One stays on the ground and has a crest; the other lives in herds, not scattered about like the former; its color, however, is like the former's, though its size is smaller and it does not have a crest; it is eaten.

644. Literally "the soft-head." Perhaps the shrike.
645. Probably the little cormorant (cf. 593b18).

9.26
The Woodcock and the Starling

The woodcock is caught in gardens with nets; its size is that of the chicken, its beak long, its color like that of the francolin. It runs fast; it is moderately friendly to human beings.

The starling is variegated; its size is that of the blackbird.

9.27
The Ibises

The ibises in Egypt are of two sorts: the white ones and the black ones. The white ones occur in the rest of Egypt, but not in Pelusium, while the black ones do not occur in the rest of Egypt, but occur in Pelusium.

9.28
The Little Horned Owls

Among the little horned owls, some are always present in all seasons, and are called the "forever little horned owls"; they are not eaten because they are inedible. The others occur sometimes in fall; they appear for one day or for at most two; they are **618^{a}1** edible and very popular. They differ from the so-called forever little horned owls in (one might almost say) no respect other than fatness. Also, they are voiceless, while the others have a call. As regards their generation, nothing has been observed, except that they appear when west winds are blowing; that, though, is evident.

9.29
The Cuckoo

The cuckoo, as was said elsewhere,[646] does not build a nest, but lays in the nests of other birds, especially in those of the wood pigeons, and in that of the *hypolais* and the lark on the ground, and in a tree in that of the so-called greenfinch. It lays one egg, but does not brood on it itself; instead, the one in whose nest it has been laid is the bird that hatches and nourishes the chick. And, so they say, when the cuckoo chick grows, the mother bird ejects her [own] chicks, which perish in this way. Others say that after killing them, the one who is rearing them actually gives them to the cuckoo chick to eat; for because the cuckoo chick is beautiful she rejects

646. 6.7.

her own as unworthy. They agree to most of this as having come from their own observations. But about the destruction of the bird's chicks, they do not all say the same thing. Instead, some say that the cuckoo herself returns and eats the chicks of the host bird; some that, because of its superior size, the cuckoo chick is first to snap up the nourishment being offered, with the result that the other chicks perish from starvation; and some that, being stronger, it kills them while being nourished together with them.

It seems that the cuckoo is practically wise in doing its begetting of offspring; for because it well knows its own cowardice, and that it is unable to aid them, because of this it makes its own chicks into, as it were, suppositious children,[647] in order to save them. For this bird exceeds all in cowardice; for it has its feathers plucked out by the little birds and flees from them.

9.30
The Footless Birds

As for the footless birds, which some call the *kupselos*, that they are like the swallows was said previously;[648] in fact, it is not easy to distinguish them from the swallow, except that their shank is shaggy. They nest in long hive-like structures made of mud, with barely an entrance. They build the nests under cover, under rocks and in caves, so that they avoid both wild beasts and human beings.

The so-called *aigothêlas*[649] is a mountain bird, in size a little bit bigger than a blackbird, but smaller than a cuckoo. It lays two eggs or three at most; in character it is lazy. It flies to the female goats and milks them, hence its name. They say that, when it has milked the udder, the milk ceases and the goat goes blind. The bird is not sharp-sighted during the day but sees at night.

9.31
The Ravens

The ravens, in small spots and where there is not enough nourishment for more, occur only as a single pair. When their chicks are able to fly, they first eject them [from the nest], and then chase them away even from the place. The raven lays either four or five eggs. Around the times when the mercenaries of Medius were destroyed at Pharsalus,[650] the places around Athens and the Peloponnese became destitute of

647. I.e., not really the offspring of the ones who suppose them to be their own.
648. 487b24–31, but not mentioning the *kupselos* as such.
649. Literally, "goat-sucker."
650. In 404 BC or 395 BC.

ravens, suggesting the possession of some perception of communication issuing from each other.

9.32
The Eagles

Of the eagles there are several kinds. One is the so-called white-tail; it occurs in plains, groves, and cities; some call it the "fawn-killer." It flies both to the mountains and to the woods because it is confident; the remaining kinds rarely visit plains and groves.

Another kind of eagle is called the *plaggos*, which is second in size and strength. It dwells in mountain glens, hollows, and lakes, and is called the "duck-killer" and the *morphnos*. It is the one Homer mentions in the expedition of Priam.[651]

Another is black in color, the smallest in size, and the strongest of them; it dwells in mountains and woods and is called the "black eagle" and the "hare-killer." It is the only one that rears up its offspring and leads them out of the nest. It is quick-striking, orderly, unenvious, fearless, pugnacious, and keeps silent;[652] for it neither complains in low tones nor screams.

Further, another kind has dusky wings, a white head, a very large size, very short feathers, an elongated rump, and is like a vulture; it is called the "mountain stork" and the "sub-eagle,"[653] and dwells in groves. It has the same bad features as the others, but none of the good ones; for it is caught and pursued by the ravens and the other birds; for it is heavy, lives badly, carries off dead animals, is always hungry, and cries aloud and complains in low tones.

There is another kind of eagles, which are called "sea eagles." They have a neck that is long and thick, feathers that are curved, and a rump that is broad. They dwell near the sea and headlands. When seizing prey and unable to carry it off, they are often pulled down into the depths.[654]

Further, there is another kind of eagles, which are called the "pure-bred ones." They say that among the other birds too these are the only ones that are pure-bred; for the other kinds are mixed and adulterated by each other, and so are the eagles, the hawks, and the smallest birds. This is the largest of all the eagles; it is larger than the bearded vulture[655] and half again as big as the [white-tailed] eagles; its color is yellow. It seldom seen, like the so-called *kumindis*.[656]

651. *Iliad* 24.316.
652. Alternatively, "emits sounds of good omen."
653. Alternatively, "the *gupaetos*."
654. $620^{a}7$–10.
655. Cf. $592^{b}5$.
656. $615^{b}5$–10.

The eagle's time for working and flying is from lunchtime to evening; for it settles from dawn until the marketplace is full.

As eagles grow old, the upper beak grows ever more curved and in the end they die of starvation. It is said in a story, in fact, that this happens to it because once, when it was a human being, it wronged a guest-friend.

It puts away any residual nourishment for the chicks; for because it is not easy to procure it each day, they sometimes have nothing to bring from outside. They strike with their wings and tear with their claws anyone they catch inspecting around their nests. They build these not in the plains but in high places, mostly in precipitous rocks, but nonetheless in trees too. They rear the chicks until they become able to fly; then they expel them [from the nest] and drive them out of the entire place around it. For one pair of eagles hold power over a large place; which is why they do not allow others to encamp nearby.

They hunt not from places near their nests, but after having flown a long distance away. When one has hunted and caught something, it sets it down and does not immediately carry it off; instead, after trying its weight, it lets go of it [if it is too heavy]. Even the hares, it does not catch immediately, but after letting them go ahead
619b1 into the plain; and then it does not immediately come down to the ground, but from greater to ever lesser [heights] by slow degrees. It does both of these for safety, so as not to be caught in an ambush. Also, it settles in high places because of its slowness in rising from the ground. If flies high in order to look down on the largest place possible; that is why people say that it alone of the birds is divine.

All of the crook-taloned birds very seldom settle on rocks because, due to their crookedness, the hardness presents an obstacle.

The eagle hunts the hares, the fawns, the foxes, and all the others that it can overpower. It is long-lived; this is clear from the fact that its nest remains in the same place for a long time.

9.33
A Scythian Bird

In Scythia there is a kind of bird that is no smaller than the bustard. It gives birth to two chicks, but does not brood on them; instead, it leaves them hidden in the skin of a hare or fox. It guards them on top of a high tree, when it does not happen to be hunting; and if anyone climbs up, it fights him and strikes him with its wings, like the eagles.

9.34
Night Birds

The owls, the night ravens, and all the rest that are unable to see during the day procure their nourishment by hunting at night; they do not do this the entire night,

but as long as evening lasts[657] and around dawn; they hunt the mice, the lizards, the *sphondulê*,[658] and other small animals of this sort.

The so-called bearded vulture is kind to its offspring, lives well, carries meals back to the nest, is gentle, and rears not only its own offspring, but also those of the eagle. For when the eagle has ejected them from the nest, the bearded vulture, having taken them, nourishes them; for the eagle expels them prematurely, still in need of the means of life and not yet able to fly. The eagle, it seems, ejects its offspring because of envy; for it is by nature envious and ravenously hungry, and quick in seizing food besides. And it seizes large quantities of it, when it does seize it. It envies the chicks as they mature, then, because they become good eaters, and it tears at them with its claws. The chicks also fight among themselves over their place in the pecking order and their nourishment. The eagle expels them and strikes them. When they are being expelled, they cry aloud, and so the bearded vulture takes charge of them.

The bearded vulture has a white film over its eyes and a deformation in them. The sea eagle, by contrast, is very sharp-sighted, and compels its offspring, while they are still featherless, to look toward the sun; the one that refuses, it strikes and turns around; and whichever one of the two[659] is the first to get tears in its eyes, it kills; the other, it rears. It spends its time by the sea and lives by hunting the sea birds, as was said.[660] It hunts by catching them one by one, watching for one emerging from the sea. When the bird comes up and sees the sea eagle, it is frightened and plunges down again, so as to pop up somewhere else. But the sea eagle, because of its sharp sight, keeps flying after it until it either drowns the bird or catches it on the surface. For it does not attack birds in gatherings; for they keep it off by splashing it with their wings.

9.35
The Kepphos

The *kepphos*[661] are caught with foam; for they gulp it down; that is why they hunt them by sprinkling them with it. Their other flesh has a good odor, excepting the rump, which smells of black shoreweed.[662] They become fat.

657. Reading ἀλλ᾽ ἄχρι ἑσπερίου.
658. Probably an insect similar to a cockroach or *Blatta orientalis*.
659. $563^{a}17$–19.
660. Implied at $619^{a}6$–8; cf. $593^{b}23$–24.
661. $593^{b}14$.
662. $598^{a}5$.

9.36
The Hawks

Among the hawks, the strongest is the buzzard; second, the merlin; third, the *kirkos*.[663] The starry hawk, the wood pigeon killer,[664] and the *pternis* are other sorts. The broader hawks are called "half-buzzards." Others are the *perkos*, the sparrow hawks, the smooth hawks, and the toad-catchers. These live best and fly along the ground.

The kinds of hawks that differ from each other, some say, are no fewer than ten: for some strike and seize the common pigeon when it is sitting on the ground, but do not touch it when it is flying; others hunt it when it is sitting in a tree or something else of the sort, but do not attack it when it is on the ground or in the air; others do not touch it when it is sitting on the ground or on anything else, but try to seize it in flight. They say that the pigeons recognize each of these kinds, so that when one of them is flying toward them, if it is one of those that hunt in the air, they remain wherever they happen to be sitting; on the other hand, if the one flying toward them is one of those that strike on the ground, they do not remain there but instead fly away.

In the part of Thrace once called Cedripolis, people hunt the small birds in the marsh together with hawks; for the people, holding sticks, beat the reeds and the **620b1** undergrowth to make the small birds fly, while the hawks, appearing in the air above, pursue them; out of fear the birds fly down to the ground again; the people strike them with their sticks and seize them, and the hunters give a share to the hawks; for they throw some of the birds up in the air and the hawks catch them.

Also, around Lake Maeotis too they say that the wolves[665] are accustomed to the fishermen, and when they do not give them a share of the catch, they destroy their nets when they are drying on the ground.

As regards the birds, then, this is their mode.

9.37
The Marine Animals

As regards the marine animals too, it is possible to observe many craft-like things relating to the lives of each of them. For the stories repeated about the fishing frog—the so-called fisherman—are true, as are the ones about the torpedo fish. For the fishing frog is furnished with things hanging in front of its eyes, which are hair-like lengthwise, with a round thing at the tip, as if set on each side to serve as bait; when it has stirred up the sand or the mud, it hides itself, and lifts up the hair-like parts;

663. 9.36.
664. 615b7.
665. Perhaps λάρους ("gulls") should be read.

when the small fishes strike, it draws the parts in until it has brought them close to its mouth.

The torpedo fish, catching small fishes by producing numbness in the ones it is about to overcome with an instrument that it has in its body, nourishes itself on them; it hides itself in the sand and mud, and catches all the ones that, as they swim toward it, get numbed when they approach it. Some people have seen this happening themselves. The stingray also hides itself, though not in the same way.

There is a sign that these fishes live in this way; for they are often caught with mullets inside them, though they are themselves the slowest and mullets the fastest fishes. Next, when the fishing frog no longer has the things at the ends of the hairs, it is thinner when it is caught, while the torpedo fish is seen to cause numbness even in the human beings.

The hake, the ray, the *psêtta*,[666] and the angel fish hide in the sand and, when they have made themselves invisible, fish with the things in their mouth that the fishermen call "little fishing rods." The small fishes come to them taking them for seaweed, on which they nourish themselves.

Wherever the *anthias* is seen, there is no savage beast present; the sponge-divers use it as a sign when they are diving, and call these the "sacred fishes." But it seems to be a coincidence,[667] just as wherever there are snails, there is neither pig nor partridge; for both eat snails. **621^{a}1**

The sea snake[668] has a color and a body much the same as that of the conger eel, except that it is more tapered[669] and more violent. If it is frightened[670] and set free, it burrows down into the sand, boring a hole quickly with its snout; it has a mouth more pointed than that of the snakes.

The so-called sea millipede, when it has swallowed the hook, turns itself inside out, until it has expelled the hook; then it turns its inside back in again. The sea millipedes go toward things with an odor of greasy steam,[671] just like the land millipedes. They do not bite by means of their mouth, but by means of contact with the whole of their body, like the so-called sea nettles.

Among the fishes, the ones named "foxes,"[672] when they perceive that they have swallowed a hook, rescue themselves from this like the millipede; for they run a long way up the fishing line and bite it off; for they are caught in some places on lines with multiple hooks in rapidly flowing and deep waters.

The bonitos, for their part, collect together when they have seen some savage beast, and the largest of them swim around, and if it touches one, they drive it off.

672. 565^{b}1, 566^{a}31.

They have strong teeth and cases have been observed of other fishes, even the *lamia*,[673] covered with wounds after falling among them.

Among the river fishes, the male sheatfish takes a lot of care of the offspring; for the female departs after laying the eggs, but the male keeps egg-guard where the largest quantity of embryo has been composed, providing no other benefit except that of keeping off the other small fishes lest they plunder the offspring; and he does this for forty or fifty days, until the offspring have grown and are able to flee from the other fishes. He is recognized by the fishermen wherever he happens to be egg-guarding; for, when keeping off the little fishes, he darts at them and makes a moaning sound. He stays by the eggs with such family affection that sometimes the fishermen, if the eggs are attached to the deep roots, draw them up to the lowest place they can. Nonetheless, he does not abandon the offspring, but if it so happens,[674] he is quickly caught with a hook because he is snatching up the small fishes that approach; but if he is accustomed to this and to biting hooks, he still does not forsake the offspring, but instead, by crushing them with his strongest teeth, he destroys the hooks.

621b1

All the fishes, both the migrants and the stationary ones, feed in those places in which they were born and in places like them;[675] for the nourishment proper to each is in these places. Those that wander around the most are the carnivorous ones; and pretty much all are carnivorous except for a few—for example, the mullet, the saupe fish, the red mullet, and the *chalkis*. As for the so-called *phôlis*, the mucus it discharges gets plastered around it and becomes like a lair.

Among the hard-shelled footless animals, the scallop moves the most and the furthest, flying by its own agency;[676] for the purpura and those like it move forward to a very small extent.

From the straits of Pyrrha the fishes swim out in winter because of the cold, except for the goby (for the strait is colder); as soon as it is spring, they swim back in. In the strait the parrot wrasse does not occur, nor does the *thritta*, nor any other of the more brightly colored fishes; nor the dogfishes, the spiny dogfishes, the crayfishes, the octopuses, the *bolitaina*,[677] and certain others; and among those that grow in the strait, the white goby is not a deep-sea fish.

Among the fishes, the egg-laying ones are at their prime in spring, until they have given birth, the live-bearing ones in fall, and in addition to these, the mullets, the red mullets, and all the others of that sort. The fishes around Lesbos—both the deep-sea fishes and the strait-dwelling ones—give birth in the strait; for they mate in the fall and give birth in the spring. The selachians also intermingle in fall, the males with the females, at their mating, but in spring they swim in, having separated until they give birth; at the time of their mating, many are caught yoked together.

673. 540b18.
674. Rejecting the addition of νέος.
675. 589a10–22.
676. 528a30–32.
677. 525a19–20.

Among the soft-bodied animals, the cuttlefish is the most cunning, and alone uses the ink for concealment—and not only when frightened; the octopus and the calamary emit the ink because of fear. None of these ever emits all the ink at once; and when they have emitted it, it increases itself again. But the cuttlefish, as was said, often uses the ink for concealment, and having made a feint to the front, turns into the ink. Further, it hunts with its long tentacles not only the small fishes, but often even the mullets. **622^a1**

The octopus, though foolish (for it in fact comes toward a person's hand if he puts it under water), is a good household manager;[678] for it collects everything together in the lair where it happens to live, and having consumed the most useful parts, it ejects the shells and the cases of the crabs and shellfishes and the bones of the small fishes. Also, it hunts the fishes by changing color and making it like whatever rocks it comes near to. It does the same thing when it is frightened. It is said by some people that the cuttlefish also does this; for they say that it makes its own color like that of the place where it spends its time. But among the fishes, the angelfish alone does this; for it changes its color like the octopus.

The majority of the octopus kind does not live for more than a year; for by nature it dissolves easily. There is a sign of this: for when it is being pounded,[679] it always loses something and, in the end, disappears. The females, after giving birth, are more subject to this, and become sluggish, and do not perceive that they are being tossed about by the waves, and it is easy to dive down and catch them by hand; they become slimy, and no longer hunt things that are nearby. The males become leathery and viscous.

A sign of their not living for more than a year seems to be the fact that after the generation of the baby octopuses—at any rate, in summer and toward fall—it is no longer easy to see a large octopus, while a little before that time the octopuses are at their largest. When the eggs have been laid, both the male and the female are said to become so old and weak that they are eaten by the small fishes and easily dragged from their lairs, while previously they suffer nothing like that. Further, they say that the small young octopuses suffer nothing of that sort after their generation, but rather are stronger than the larger ones. The cuttlefish also does not live longer than a year. The only soft-bodied animal to go out onto dry land is the octopus; it moves by walking on the rough ground, but it avoids the smooth. In other parts the animal is strong, but weak in the neck, when one squeezes it. **622^b1**

As regards the soft-bodied animals, then, this is their mode.

As for the clams,[680] they say that the ones that have a thin, rough shell produce around themselves a sort of hard thorax, and make this larger when they become larger, and that come out of this as from a sort of lair or house.

678. *NE* 1141^b32.
679. To tenderize it.
680. 528^a22–26.

The nautilus octopus too,[681] both in its nature and in what it does, is remarkable; for it sails on the sea, when it has made its ascent from the depths; it ascends with its shell turned downward, in order to go up more easily and navigate with it empty, but when it has surfaced, it turns it upward again. It has a web between its tentacles up to a certain point; it is like what is between the toes in the web-footed [birds], except that in those it is thick, while in these it is thin and spiderweb-like. It uses this as a sail, when there is some wind; in place of steering oars it lets down two of its tentacles by the sides. If it is frightened, it sinks down into the sea by filling its shell [with water]. Concerning its generation and its growth together with that of its shell no exact observation has yet been made, but it seems not to come to be from mating, but to grow like the other shellfishes.[682] It is also not yet clear whether, when stripped of its shell, it is capable of living.

9.38
The Insects

Among the insects the most industrious animals—and even compared to pretty much all the other animals—are the ant kind and the bee kind, and further, the hornets, the wasps, and (one might almost say) all the ones that are of the same kind as these. Among the spiders, the smoother[683] ones are the most lithe[684] and the most craft-like as regards their life. The work done by the ants is obvious for all to see, and the way they always go on one path, put aside nourishment and store it; indeed, they even work at night when there is a full moon.

9.39
The Spiders

Of the spiders and the venom-spiders there are many kinds. Of the biting venom-spiders there are two: one, which is like the so-called wolf-spiders, is small, variegated, pointy, and good at jumping, and is called the "flea"; the other is larger, black in color, with long front legs, sluggish in movement, walks softly, is not strong, and does not jump. Of all the others, the ones the medicine-makers provide, some have no bite,
623ᵃ1 others a weak one. The so-called wolf-spiders are another kind.

The small kind of spider does not weave a web; the larger kind weaves a rough poor-quality web on the ground and in dry-stone walls; it always builds the web over the openings and, while staying inside, watches over the starting-threads, until

681. 525ᵃ20–26.
682. 5.15, *GA* 3.11.
683. 555ᵇ11.
684. Or, perhaps, "slimmest."

something moves them when it falls in; then it attacks. The variegated kind builds a small poor-quality web under the [branches of] trees.

There is another, third kind of spider that is the wisest and the smoothest[685] one; for the female weaves by first stretching threads to the limit points of her web in every direction; then she lays down the spokes from the middle (she grasps adequately where the middle is); into these she inserts the woof threads, as it were, and then weaves them together. She makes her lair and the place to put aside the prey elsewhere, but hunts from the middle, where she is keeping watch. Then, when something has fallen in and the middle has been moved, she first binds it and winds the web-threads around it until she has made it helpless; after that, she lifts it up and carries it away; if she happens to be hungry, she sucks out its juice (for this is her pleasant reward); otherwise, she sets off to hunt again, having first mended the break in the web. If in the meantime anything has fallen in, she first goes to the middle, and from there goes back to what has fallen in, just as at the start. If something damages the spiderweb, she starts the web again when the sun is going down or rising, because it is mostly at those times that beasts fall in. It is the female who does the work and hunts; the male shares in the pleasant rewards.

Among the smooth spiders that weave a dense web there are two kinds, one bigger, one smaller. The first, which has long legs, keeps watch while suspended below the web, in order that the beasts not be frightened and take care, but fall in above her (for because of her size she is not easily hidden). The second, which is better proportioned, hides herself in the upper part of the web in a small hole.

The spiders are able to emit web immediately after birth, not from inside as a residue, as Democritus says, but from off the body like tree-bark, or as the animals do that shoot out their hairs—for example, the porcupines. The spider attacks and winds web around even the larger animals, since it throws it around even the small lizards, running around their mouth[686] emitting web until it has closed the mouth. **$623^{b}1$** Only then does it approach and bite it.

As regards these animals, then, this is their mode.

9.40
The Bees

There is a kind of insects that are not named by a single name, but that all have a shape of the same kind. These are all the ones that make wax combs—for example, the bees and those of much the same shape. There are nine kinds of these, six of which are herd animals: bees, the king bees, the drones that are among the bees, the annual wasp, and further, the hornet, and the *tenthrêdôn*.[687] The solitary ones are

685. Or, perhaps, "subtlest."
686. Reading στόμα.
687. Perhaps the wasp that nests in the earth. See $629^{a}31–^{b}2$.

three: the small siren, which is white;[688] another siren, which is larger, black, and variegated; and third, the so-called bumblebee, which is the largest of these.

The ants, for their part, hunt nothing, but collect things readymade; the spiders produce nothing and put nothing aside,[689] but only hunt their nourishment. But of the nine kinds just mentioned, the rest of which will be spoken about later,[690] the bees hunt nothing but produce their nourishment themselves and store it away; for the honey is nourishment for them. They make this clear when the beekeepers attempt to remove the combs; for when the bees are being fumigated and are suffering severely from the smoke, it is then especially that they eat the honey, while at other times they are not seen to do so very much, as if they are being thrifty with it and putting it aside for their nourishment. They have another nourishment too which some call *kêrinthos*;[691] this is inferior and has a fig-like sweetness; they bring it on their legs like the wax.

There is much variation regarding the work done and the mode of life of these insects. For after the hive has been given to them clean, they build the wax combs, bringing the tears of juice from the various flowers and the trees, from the willow, the elm, and others that produce a lot of gum. They also smear the bottom [of the comb] with this on account of the other beasts. The beekeepers call this *konisis*.[692] They also narrow the entrances by building, if they are wide.

They first fashion the combs in which the bees themselves come to be, then those in which the so-called kings and the drones come to be. They fashion their own all the time, those of the kings when not many offspring are generated, and those of the drones if the honey gives signs of being plentiful. They fashion those of the kings near their own, and these combs are small, and those of the drones against these; these are smaller in size than those of the bees. They start the comb-webs from above, from the top of the hive, and below producing many comb-webs woven together, until they reach the bottom. The openings, both for the honey and for the grubs, have two entrances; for there are two openings on a single base, like that of the double-cups,[693] one inside and one outside. The comb-webs attached to the hives at the starting-points of the combs, extending in a circle for as much as two or three rows, are willow and empty of honey; the fuller combs are the ones most plastered over with wax.

At the entrance of the hive, the first part of the entryway is smeared all over with *mitus*; this is deep black, and for the bees is a sort of by-product from the wax, with an acrid odor; it is a remedy for stings and abscesses of this sort. The smearing that is contiguous to this is *pissokêros*, which is less pungent and less medicinal than *mitus*.

Some say that the drones fashion combs by themselves both in the same hive and in the one single comb they divide with the bees; they make no honey, however, but nourish both themselves and the young on that of the bees. The drones spend most of their time inside the hive; if they do fly out, they are borne upward to the sky in a stream, whirling around and taking exercise, as it were. When they have done this, they come back inside and eat their fill.

The kings do not fly out, except with the whole swarm, neither for getting food nor for anything else. They say too that if the swarm has gone astray, they turn back until they find the leader by his odor. It is also said that he is carried by the swarm when he is not able to fly, and that if he perishes, the swarm perishes; but if they do survive for a certain time and make combs, no honey is produced, and they quickly perish.

The bees collect the wax in scrambling quickly up against the blossoms with their front feet; they wipe these off onto the middle ones, and the middle ones into the **$624^{b}1$** hollows of the back ones; and having filled them full in this way, they fly off, and are clearly weighed down. On each flight the bee does not go to flowers distinct in form—for example, it goes from iris to iris, and does not touch any other, at any rate, until it has flown back to the hive. When they have arrived at the hive, they shake themselves, and three or four bees attend to each one. What they receive is not easy to see, nor has their mode of working on it been seen; but the collecting of wax has been observed on olive trees: because of the density of their leaves the bees remain in the same place for a longer time.

After this they nest. Nothing prevents young bees, honey, and drones from being present in the same comb. If the leader is alive, they say that the drones come to be separately; otherwise they come to be in the bees' cells by the bees, and these ones become more spirited; that is why in fact they are called "stinged," not because they have stings, but because, though they wish to strike, they are not able to. The cells of the drones are larger. Sometimes the bees fashion the combs of the drones to be separate by themselves, but for the most part, they fashion them among those of the bees; that is why people cut them out.

There are several kinds of bees, as was said previously.[694] There are two kinds of leaders: the better one is yellowish-red, the other black and variegated; their size is double that of the worker bees. The best is small, round, and variegated; another is large and similar to the hornet. Another is the so-called robber, black with a flat abdomen. Further, the drone; in size this is the largest of all, but stingless and sluggish.

There is a difference between the bees that come to be from those that forage from cultivated plants and the bees that come to be from those that forage from mountain ones; for those from the ones living in the woods are hairier, smaller, more industrious, and more bad-tempered.

694. $553^{a}25–27, {}^{b}7–11$ (more or less repeated here).

The worker bees make the combs even and also the outer covering entirely smooth; further, the comb is of a single sort—for example, entirely for honey, or for the young, or for drones. But if it happens that they produce all of them in the same comb, there will be one continuous form constructed by means of a hold.[695] The long
625ᵃ1 bees, by contrast, make the combs uneven and the covering swollen up like that of the hornet; and further, the seed and the other things are not placed in order, but as luck would have. From these come the bad-quality leaders, many drones, and the so-called robbers, but very little or no honey.

The bees brood on the combs and concoct them; if they do not do this, they say that the combs are destroyed and become covered in cobwebs.[696] And if they are able to gain possession of the rest of the comb by brooding on it, this other part becomes like a piece eaten away; otherwise, both parts are destroyed. In the destroyed parts small larvae come to be which grow wings and fly away.

Also, the bees set upright the combs that are falling over, and put supports under them, in order to be able to pass underneath; for when they have no route by which to approach, they cannot brood on them, and they become covered in cobwebs.

The robber and the drone, once they have come to be, do no work at all, but damage that of the others. When they are caught, they are killed by the worker bees. They also kill violently the majority of the leaders, especially the bad-quality ones, in order that there not be many leaders to break apart the swarm. They mostly kill them when the hive is not generating many offspring and no release of swarms is about to occur; for at these times they even destroy the combs of the kings (if they have been established), as being the ones that lead out the swarms.

They also destroy the combs of the drones if there are indications of a shortage of honey and the hives are not well supplied with honey. It is then that they fight most about the honey with those who are removing it, expel the drones that are present, and are often seen sitting apart in the hive.

The small bees fight violently with the long kind and try to expel them from the hives; if they prevail, it is believed that this hive becomes exceedingly good. But if the others are left in control of themselves, they idle, in the end produce nothing good, and die themselves before fall. Whenever the worker bees kill, they try to do so outside the hive; if one dies inside it, they likewise take it out.

The so-called robbers not only damage the combs in their own hives, but also, if
625ᵇ1 they are unnoticed, enter those of others; if caught, they are killed. It takes work to go unnoticed; for there are guards at every entrance, and even if the robber himself got in unnoticed, due to overfilling himself he is unable to fly, but rolls around in front of the hive, so that it takes work for him to escape.

695. Reading ἀντλίας. The idea, perhaps, is that the comb is like the hold (*antlia*) of a ship in which cells of different sorts are contained within a single uniform structure.
696. 605ᵇ9–11, 626ᵇ17–19.

The kings themselves are not seen outside otherwise than together with a swarm; in the process of swarming, the rest of the bees appear in close order around the king. When swarming is about to occur, a monotonous and special sound is made for several days, and two or three days before a few bees fly around the hive. Whether the king occurs among these has not yet been observed, because it is not easy to do so. When they have collected together, they fly off and form separate swarms around each of the kings. But if a small swarm happens to settle down near a large one, the small swarm migrates to the large one, and if the king they have abandoned follows along with them, they destroy him. As regards departure and swarming, then, this is the mode in which they occur.

There are bees assigned to each sort of work—for example, some bring juice from flowers, some bring water, some smooth and set right the combs. They bring water when they are nourishing offspring. They do not settle on any animal flesh, nor do they eat cooked food. There is no accustomed time for them to start to work, but if they have the requisite provisions and live well, it is more in the spring of the year that they undertake their work, and when the weather is good, they work continuously. Also, a young bee, on the third day after it has cast off [its membrane], immediately goes to work, if it has nourishment. And when a swarm is settled somewhere, some bees turn aside to search for nourishment, and then come back again.

In hives that are thriving, bee production is interrupted for only around the forty days after the winter solstice. Whenever the young have grown, they put nourishment beside them, and put on a coat of wax; when it is able, the young bee breaks open the covering and comes out. The beasts that come to be in the hives and damage the combs are cleaned out by the worker bees, but the other bees, because of their badness, look with indifference on the destruction of their works.

When the beekeepers are removing the combs, they leave the bees nourishment **626^{a}1** for the winter; if it is sufficient, the hive is preserved; otherwise, if there is wintery weather, they die there; but if the weather is good, they abandon the hive. For nourishment they use honey both in summer and winter; but they also put aside another nourishment resembling wax in its hardness, which some name *sandarakê*.[697]

The bees are injured the most by the wasps, the birds called "titmice," and further, by the swallow and the bee-eater. They are hunted by the marsh frogs too when they go for water and encounter them; that is also why the frogs are chased by the beekeepers from the marshes where the bees get water, and why they also remove the wasp nests, the swallows, and the bee-eater nests that are near the hives. Bees flee from no animals except themselves. But their battle is both against themselves and against the wasps. Away from the hive they injure neither each other nor any other animal, but near the hive they kill any they overpower.

Those that sting perish because the sting cannot be removed without the intestine; for often the bee is preserved, if the person stung takes care and squeezes out the

697. Usually red sulfide of arsenic ($604^{b}28$), but here probably beebread ($554^{a}17$).

sting; but when it loses its sting, the bee dies. They kill large animals when they sting them—for example, a case has been observed of a horse being killed by bees. The leaders are the least bad-tempered and sting least.

The bees that die are carried out of the hive. And in all other respects the animal is most cleanly; that is why in fact they often discharge their residue while flying, because it is foul-smelling. They are annoyed, as was said,[698] by foul-smelling odors and by those of perfumes; that is why, in fact, they sting those who use them.

They die because of various coincidences, especially when the leaders become numerous and each leads away a part of them. Also, the toad destroys the bees; for coming to the entrance of the hive, it blows in, and watching for them as they fly out, eats them. It can suffer nothing bad from the bees, but the person taking care of the hive kills it.

626b1 As for the kind of bees that was said[699] to be of bad quality and to make the combs rough, there are some beekeepers who say that it is mostly the young bees that do this, because of lack of knowledge (the current year's bees are the young ones). Likewise, the young bees do not sting in the same way either; that is why the swarms can be carried; for they consist of young bees. When the honey has started to come to an end, the bees expel the drones, and the beekeepers throw in figs and sweet things for these.

The older bees work inside the hive, and are hairy because they remain inside, while the young bees fetch from outside and are smoother. Also, they kill the drones when they no longer have space to work; for they are in the innermost part of the hive.

A case has been observed where, when a hive had become unhealthy, some of the bees went to another hive and, being victorious in the fighting, carried out the honey. Then, when the beekeeper was killing them, the other bees came out to get vengeance and defend themselves, but did not sting him.

Diseases[700] mostly attack hives that are thriving, including the so-called *klêros*; this is when small larvae occur on the floor of the hive, from which, when they grow, spiderwebs of a sort come to occupy the whole hive, and the combs putrefy. Another disease is like a sort of laziness that occurs in the bees along with a foul odor in the hives.

Thyme is a source of food for the bees, and the white is better than the red. The place of the hive should not be warm in the stifling heat of summer, but in winter it should be warm. They especially become sick when the plant they are working on is mildewed. When the wind is strong, they carry a stone on themselves as ballast against the wind. They drink, if there is a river nearby, from nowhere else but from

698. Perhaps 623b20.
699. 625a4.
700. 8.27.

there, having first deposited their load; but if there is no river, they drink elsewhere, vomit up the honey,[701] and proceed immediately to work.

They have two seasons for working on the honey, spring and fall. The spring honey is sweeter, paler, and altogether better than the fall honey. The better honey comes from new wax and young plants. The red honey is inferior because of its honeycomb; for it is destroyed like wine by its container; that is why it needs to be dried. When the thyme is in flower and the comb becomes full, this honey does not solidify. It **627ª1** is the golden honey that is good; the pale does not come from pure thyme, but it is good for eyes and sores. The weak part of the honey always floats to the surface and should be removed; the pure honey is underneath.

When the woods are in bloom, the wax is worked on; that is why it is then that one should take the wax out of the beehive; for then they go to work immediately. The plants they fetch from are the following: the *atraktullis*,[702] the honey lotus, the asphodel, the myrtle, the flowering reed, the chaste tree,[703] and the broom. When they are working on the thyme, they mix in water[704] before smearing over the comb.

All the bees discharge their excrement, as was said,[705] either while flying or else into one comb. The small bees are more industrious than the large ones, as was said;[706] they have battered wings, a dark color, and are sun-burnt. The bright and resplendent ones, just like [pale] women, are lazy.

The bees seem to like rattling noises too, which is why, they say, people collect them into the hive by rattling with pots and pebbles; it is not clear, however, whether they hear anything at all,[707] or whether they do this due to pleasure or to fear.

The bees expel both the lazy ones and those that are not thrifty. The sorts of work, though, have been divided, as was said previously,[708] and some work on combs, some on the honey, some on *erithakê*;[709] also, some are fashioning combs, others carrying water to the cells and mixing it with the honey, others going to work. At daybreak, they keep silent, until one bee awakens them by buzzing two or three times. Then they all fly out together to work; when they return, they are noisy at first, but little by little become less so, until a single bee flies around buzzing, as if giving the signal for sleep; then suddenly they get silent.

The hive is diagnosed to be strong by its noise being loud and by the movement of bees going out and coming in; for then they are working on the larvae.

709. $554^{a}17$.

They are most hungry when they start working after winter. But they become lazier, if one leaves too much honey when harvesting [the combs]; instead, one should leave combs in proportion to the quantity of bees; for they also work with less spirit if too few are left. They also become lazier if the beehive is large; for they labor with less spirit. The harvest from a hive is a *chous* or three half-*choes*, and from thriving ones, two *choes* or five half-*choes*. [Only] a few hives give three *choes*.

The sheep are an enemy of the bees, and so are the wasps, as was also said previously.[710] The beekeepers hunt the wasps, putting out a dish and throwing meat into it; when a number of wasps light on it, they cover it with a lid and put it on the fire. When a few drones are present, it benefits the hive; for they make the bees more industrious.

The bees foretell both storm and rain. There is a sign of this; for they do not fly off [despite the] good weather, but crowd together by the hive, by which the beekeepers know that they are expecting a storm. When they hang from each other in the hive, it is a sign that the swarm is about to leave. But the beekeepers sprinkle the hive with sweet wine when they perceive this.

It is advantageous to plant around the hives wild pear trees, beans, Median grass,[711] Syrian grass, *ôchros*,[712] myrtle, poppy, creeping-thyme, and almond.

Some beekeepers recognize their own bees in the place where they get food by having dusted them with flour.

If spring is late, or if there is a drought, or when there is mildew, the bees have less seed to work on.[713]

As regards the bees, then, this is their mode.

9.41
The Wasps

As for the wasps, there are two kinds. The wild ones of these are rare; they occur in the mountains, and give birth not underground but in the oak trees; in shape they are larger and more elongated, and more black in color than the others, but variegated; they all have stings, are more aggressive, and sting more painfully than the others; for in fact their sting is proportionally larger in size to that of the others. These wasps live for more than a year and are seen even in winter flying out of oak trees when they are cut down. They live in hiding during winter and spend their time in the trunks of trees. Some of them are mothers,[714] others workers, just as in the tamer ones.

710. 626a8.
711. 522b26.
712. Perhaps *Lathyrus ochrus*.
713. 553b19–23.
714. Literally, "wombs."

What the nature is of the workers and the mothers will be clear from the case of the tamer ones. For among the tame wasps there are also two kinds, the leaders, **628^{a}1** which are called "mothers," and the workers. The leaders are much larger and gentler. Also, the workers do not live for more than a year, but all die when winter comes in (it is evident that this is so; for at the start of the winter their workers become 5 sluggish, and around the solstice are not seen at all). The leaders, on the other hand, the ones called "mothers," are seen throughout the winter and go into hiding underground; for, while plowing and digging in winter, many people have seen mothers, but no one has seen workers.

The generation of the wasps is as follows. The leaders, when they have picked a 10 sheltered place at the onset of summer, fashion the combs and establish what are called small "wasp-combs"[715]—that is to say, with four openings or thereabouts—in which wasps come to be, but not mothers. When these wasps have grown, the leaders again construct other larger ones after these, and others again when these have grown, 15 so that, when fall is ending, very many of the largest wasp-combs have been produced in which the leader, the so-called mother, generates no longer wasps but mothers. These come to be up above, toward the surface of the wasp-comb, as larger larvae, in contiguous cells of four or slightly more, and in much the same way as those of the 20 leaders[716] come to be in the combs [of the bees].

After the worker wasps have come to be in the combs, the leaders no longer work; instead, the workers bring them in their nourishment. This is made evident by the fact that the leaders of the workers no longer fly out but remain quiet inside. Whether the previous year's leaders, when they have generated new leaders, are killed by the 25 new wasps, and this happens [always] in the same way, or whether they are able to live for a longer time, no one has yet observed; nor has anyone yet been seen who has himself observed old age in either a mother or in the wild wasps, or any other affection of this sort.

The mother is broad and heavy, both thicker and larger than the wasp, and 30 because of its weight, not very strong in flying; nor can they fly for a long distance; that is why in fact they sit in the wasp-combs all the time, fashioning and managing things within.

In most wasp-combs the so-called mothers are present. But there is dispute as to 35 whether they have stings or are stingless. It seems likely that, like the leaders of the **628^{b}1** bees, they do have stings but neither put them out nor strike.

Among the wasps, some are stingless like the drones; others have a sting. The stingless ones are smaller, feebler, and do not defend themselves; the ones with stings are larger and more aggressive. Some people call the latter "males," and the stingless 5 ones "females." At the approach of winter, many of those with stings are believed to lose them; but we have not yet met an eyewitness.

715. Reading σφηκωνεῖς τοὺς μικρούς.
716. I.e., the king bees.

The wasps occur more in droughts and in rugged places; they come to be underground and fashion their combs from debris and earth, each from a single starting-point, as from a root. The nourishment they use comes from certain flowers and fruits, but mostly from animal flesh. Some of the other wasps[717] have been observed mating; but whether both were stingless or had stings, or one did and the other did not, no one has yet observed. Some wild ones have also been seen mating, one of which had a sting; but concerning the other there was no observation.

The offspring does not seem to come to be from giving birth, but from the outset seems too large to be born from a wasp.[718]

If one grasps a wasp by its feet and allows it to buzz with its wings, the stingless ones fly toward it, but the ones with stings do not fly toward it. Some people use this as a proof that the first are males, the second females. Both those with stings and those without stings are caught in caverns during the winter.

Some build a few small wasp combs; others build many large ones. The so-called mothers are caught at the change of season, mostly around elm trees; for they collect the viscous and gum-like stuffs. The mothers occur in large numbers where in the previous year there were many wasps and heavy rains. They are hunted around the cliffs and vertical clefts in the ground, and it is evident that all of them have stings.

As regards the bees, then, this is their mode.

9.42
The Hornets

The hornets live not by gathering from flowers like the bees, but mostly from eating flesh (that is also why they stay around excrement; for they hunt the large flies, and when they have caught them, they remove the head, and fly off carrying the rest of the body); they also feed on sweet fruit. For nourishment, then, they use what was mentioned. They have leaders like the bees and the wasps; and these leaders are larger in size in proportion to the hornets than the leader of the wasps is in proportion to the wasps, and the leader of the bees in proportion to the bees. This one too spends its time inside like the leader of the wasps.

The hornets build their hive underground, carrying out the earth like the ants; for swarming, like that of the bees, does not occur with them or with the wasps; instead, younger ones are always added on, and by staying there, make the hive larger by carrying out the soil. The hives become very large; indeed, cases have been observed where from a thriving hive three or even four baskets full of combs have been removed. They do not, like the bees, put aside nourishment, but go into hiding for the winter, and most of them die; whether in fact they all do is not yet clear.

717. I.e., the tame ones.

718. Though in fact it is (628ᵃ18, 629ᵃ36, *GA* 721ᵃ5, 761ᵃ6).

No more than one leader comes to be in their hives, as there is in those of the bees, where the leaders of the bees break apart the hives. But when some of the hornets have strayed from the hive, they gather together on some tree and produce combs, of precisely the sort that are often seen when on the surface, and in this they generate one leader; and he, when he has emerged and grown, leads them away and settles them together with himself in a hive.

About the mating of the hornets nothing has yet been observed, nor where the offspring comes from.[719] In the bees, both the drones and the kings[720] are stingless, and some of the wasps are stingless, as was said previously,[721] while the hornets are all seen to have stings. But where the leader is concerned, it must in fact be investigated more to see whether he has a sting or not.

9.43
The Bumblebees and the Tenthrêdôn

The bumblebee gives birth to its offspring under a stone on the ground itself, in two cells or slightly more; and there also occurs the start of a poor sort of honey in these.

The *tenthrêdôn* resembles the hornet but is variegated, and its breadth is like that of the bee. Being gluttonous, it flies alone into butcher's shops, fishmongers, and such places of indulgence. It gives birth underground like the wasps, and is prolific; the *tenthrêdôn* nest is much larger than that of the wasps and more elongated. **$629^{b}1$**

As regards the bees, the wasps, and the others of this sort, then, this is their mode of working and of life.

9.44
The Lion and the Thôs

As regards the characters of the animals, as was also said previously,[722] it is possible to observe differences especially in relation to courage and cowardice, then, also in relation to mild-manneredness and wildness, even among the wild animals themselves.

For even the lion, although it is most dangerous when feeding, when it is not hungry and has fed, is very mild-mannered. In character it is neither nervous of anything nor suspicious of anything, and toward those reared with it and it is accustomed to, it is very playful and affectionate. In hunts, even when seen, it never runs away or

719. Cf. *GA* $761^{a}2$–10.
720. Cf. $628^{b}2$.
721. $628^{b}3$.
722. $588^{a}21$–25, $608^{a}11$–17, $610^{b}20$–22.

cowers in fear, but if it is compelled to withdraw because of the number of hunters, it retires gradually, walking laterally,[723] and every now and then turning its head; if, however, it reaches thick cover, it flees quickly, until it stands in plain view; then it again retires gradually. In open country, if it has been compelled by the number [of hunters] to flee in plain view, it runs stretched out and does not leap. When running, it is continuously stretched out like a hound; when it is pursuing something, however, it throws itself on it, when it is near. And what is said about it is true, that it is most afraid of fire—as Homer says in his poem: "and flaming torches which, though furious, it dreads"[724]—and that it keeps watch on the hunter who throws and hits it and hurls itself on him. But if one throws and does not hit it, though he annoys it, then if by rushing at him it can catch him, it does not injure him or hurt him with its claws, but when it has shaken and frightened him, lets him go again.

The lions approach cities and injure people mostly when they have become old, since they are unable to hunt because of their age and because their teeth have been damaged. They live for many years. In fact, a lion that was captured lame had many of its teeth broken, which some people furnish as proof that they live for many years; for this could not have happened to an animal that had not lived a long time.

There are two kinds of lions. Of these, the one that is rounder and has curlier hair is more cowardly, while the longer one with straight hair is more courageous. Sometimes they flee with their tails extended like the hounds. Once a lion was seen on the point of attacking a pig and, when it saw the pig bristle up in defense, fleeing. It cannot bear blows to its flanks, but to the rest of its body it can take many, and its head is strong. In everything it has bitten or wounded with its claws, discharges of very yellow serum run from the wounds that cannot be washed out of the bandages and sponges with anything. The treatment is the same as for wounds caused by dog bites.

The *thôs*[725] too are friendly to human beings, and neither harm people nor are very afraid of them; but they are at war with the dogs and the lions; that is why they do not occur in the same place. The small *thôs* are the best. Some people say that there are two kinds of *thôs*, others three. But it seems that there are not several kinds, but rather that, like some of the fishes, the birds, and the four-footed animals, the *thôs* also change in accord with the seasons, and have one color in winter and another in summer, and in summer become smooth and in winter shaggy.

9.45
The Bison

The bison occurs in Paeonia on Mount Messapium, which separates Paeonia from Maedica; the Paeonians call it the *monapos*. In size it is as large as a bull; it is more

723. 498b7–10.
724. *Iliad* 11.554, 17.663.
725. 507b17.

bulky than the ox; for it is not elongated. The skin when stretched out covers a seven-couch dining room. In general, its form is like that of an ox, except that it has a mane down to its shoulder like a horse; but its hair is softer than that of the horse and lies closer to the body. The color of its hair is yellowish, and the mane is deep, reaching down to the eyes, and thick. The bison's color is a mean between ashen and red, not like that of the horses called "chestnut," but its hair is rougher above and wooly below. Black ones or very red ones do not occur. They have a voiced sound like that of the ox. Their horns are crooked, turned toward each other, and useless for defense. In size they are a span or a little more, and of such thickness that each would hold not much less than a half-*chous*. The blackness of the horn is beautiful and shiny.

The forelock reaches down to the eyes, with the result that the bison sees better to the side than to the front. It has no upper teeth, like the ox and all the horned animals; its legs are shaggy; it is cloven-hoofed; its tail is too small in proportion to its size and is like that of the ox. It throws up the dust and digs like the bull. Its skin is strong against blows. Its flesh is pleasant tasting, and that is why people hunt it. When it is struck, it flees, and stands its ground when it is tired out. It defends itself by kicking and by voiding excrement, throwing it up to four rods away from itself; it employs this easily and often, and it scorches the hounds' hair so that it scrapes off. It is when the bison is agitated and frightened that its excrement does this, but when the bison is not agitated it does not scorch.

This, then, is what the form and nature of the beast is.

When it is time to give birth, they give birth in a gathering in the mountains. They first discharge excrement around the place before giving birth and make a sort of rampart; for the beast discharges a large quantity of this residue.

9.46
The Elephant

The most easily domesticated and tamest of the wild animals is the elephant; for there are many things that it both learns and is aware of, since elephants are even taught to kneel before the king. It is also keenly perceptive and in comprehension surpasses the other animals. When it has mated with one female and made her pregnant, it does not have intercourse with that one again.[726]

Some people say that the elephant lives for two hundred years, others for one hundred and twenty,[727] that the female lives pretty much the same number of years as the male, that its prime is at around sixty years, and that it is sensitive to cold winters and frosts. The animal occurs dwelling by rivers but is not a river animal. But it moves by walking even through water and goes on as long as its trunk is held above it; for it

726. $546^{b}10–11$.
727. Cf. $596^{a}9–11$.

is through this that it blows upward and does its breathing. But it is not able to swim much, because of the weight of its body.

9.47
Avoidance of Incest in Camels and Horses

Camels do not mount their mothers; even if someone forces them, they are unwilling. For once, seeing that there was not a mate, the keeper covered up the mother and put her calf to her; after mating, the cover fell off, though by then the calf had completed the intercourse; but a little later, he bit the camel-keeper to death.

631ᵃ1 It is said too that the king of the Scythians had a mare that was true to her noble stock, from whom all the colts were good. Wishing the best of these to beget offspring also from the mother, the king brought it to her in order to mate; but it was unwilling to; but when she was covered up, it mounted her in ignorance; when, after mating, the mare's face was revealed, after seeing her, the colt fled and threw itself down a cliff.[728]

9.48
The Dolphin

Among the marine animals, very many signs of mild-manneredness and tameness in the dolphin are mentioned, in particular their love and appetite for children, around Tarentum, Caria, and other places. Around Caria too, when a dolphin had been captured and wounded, a large gathering of dolphins is said to have come into the harbor until the fisherman let it go; then they all went away again together. Also, the small dolphins are always accompanied by one of the large ones for purposes of protection. Once a herd of large dolphins, together with small ones, was seen; of these, two that were left no great distance behind were seen to be swimming beneath a little dead dolphin whenever it was being carried into the depths, and buoying it up on their back, as if feeling pity for it, so that it was not devoured by some of the other beasts.

Also mentioned are some untrustworthy reports about the animal's speed; for it seems to be the fastest of all animals, both aquatic and terrestrial. Also, they leap over the masts of large ships.[729] This mostly happens to them when they are pursuing some fish for nourishment; for then, if it is escaping, they follow it down to the depths because of their hunger, and when their return to the surface becomes too long for them, they hold in their breath, as if by rational calculation, and after drawing themselves together, go off like an arrow, wishing to cover the distance by their speed in

728. Cf. 576ᵃ16–20.
729. 602ᵃ30.

order to breathe, and leap over its masts, if a ship happens to be somewhere nearby. Divers do the same thing when they have plunged to the depths; for in proportion to their own capacity they too are carried upward after drawing themselves together.

Dolphins spend their time with each other in pairs, males with females. **631ᵇ1**

One might raise a puzzle about them as to why they beach themselves on the land; for they are said to do this sometimes, when luck would have it, due to no cause.

9.49
Changes in Sexual Characteristics

Just as it happens in the case of all animals that the actions they do are in accord with their affections, so contrariwise their characters also change in accord with their actions, and often some of their parts do so too, as happens in the case of the birds. For hens, when they have defeated the males, crow in imitation of the males and try to mate them, and their crest and rump are raised, so that it is not easy to recognize that they are female; and in some even small spurs of a sort stick out.

Also, some cases have been observed of males, when the females have died, taking the female's care of the chicks, leading them around and rearing them, so that they neither still crow nor attempt to mate. There are also some birds that are so effeminate from birth that they even submit to males attempting to mate with them.

9.50
Castration and Rumination

The animals not only change, in certain cases, their shapes and character in accord with their ages and the seasons, but also when they are castrated. All animals that have testicles can be castrated. The birds and the egg-laying four-footed animals have their testicles inside near the loins; of the live-bearing terrestrial ones, most have them outside, some inside, and all at the end of the abdomen.

The birds are castrated at the rump, where they meet when mating; for if one cauterizes them there two or three times with iron, then, if the bird is already completely grown, the crest becomes pale, and it no longer crows nor tries to mate; but if it is still a young bird, neither of these affections develops as he grows.

It is the same way with human beings; for if one mutilates them as boys, the later-growing hair does not develop, nor does the voice change, but remains high-pitched; but if they have already reached puberty, the later-growing hair falls out except for that in the pubic region (this diminishes but remains), but the congenital hair does not fall out; for no eunuch becomes bald. **632ᵃ1**

The voice also changes in all four-footed animals that are castrated into that of the female. Although the other four-footed animals die, if they are not castrated when young, in the case of the boars alone, it makes no difference. But all of them, if castrated young, become larger and smoother than the uncastrated ones, but if they are already mature, they no longer grow any more.

The deer, if they are castrated when they have as yet no horns because of their age, no longer grow horns; but if they have them when one castrates them, the size of them remains the same and they do not shed them.

Calves are castrated when they are one-year-olds, otherwise they become uglier and smaller. The young bulls are castrated in the following way: laying them down and cutting the scrotum below the testicles, they squeeze them out, then they push back the roots as far as possible, and plug the wound with hair, in order that the serum flow out; and if it becomes inflamed, they cauterize the scrotum and put on a plaster. If bulls with [working] testicles are castrated, they can manifestly co-generate offspring.[730]

The ovary of female pigs is cut[731] too, so that they no longer need to be mated and instead fatten quickly. It is cut, after having starved the sow for two days, when she has been hung up by her back legs. They cut the lower part of the abdomen, about where the testicles mostly grow on the males; for there the ovary is attached to the womb; they cut off a little of it and stitch the incision together.

Female camels are cut too, when they wish to use them for war, in order that they not conceive. Some people in the uplands[732] have as many as three thousand camels. They run faster than the horses of Nesaea[733] if they run a long distance, because of the length of their stride.

In general, castrated animals grow to a greater length than uncastrated ones.

The animals that ruminate derive benefit and enjoyment from it and ruminate as
632b1 if eating. Animals that do not have two rows of teeth ruminate—for example, the cows, the sheep, and the goats. In the case of the wild animals nothing has yet been observed, except in those that are sometimes reared in captivity—for example, the deer; and this one does ruminate. All more often ruminate lying down. They ruminate most in winter, and those being nourished domestically do it for pretty much seven months; but those in herds ruminate less and for shorter periods because of feeding outside.

730. 510b3–4, *GA* 717b2–3.

731. The verb—*ektemnein*—also means "castrate," but in that sense applies only to animals that have testicles (631b21).

732. Probably inner Asia.

733. Reputedly the fastest.

Some animals with two rows of teeth ruminate too—for example, the mice from Pontus[734] and the fishes[735] (in particular, the one[736] that some call the "ruminant" after this work).

The long-legged animals are watery-boweled, while the broad-chested ones tend more to vomit, in the case of the four-legged animals, in the case of the birds, and in the case of the human beings, for the most part.

9.51
Changes in the Birds

Among the birds many change, in accord with the seasons, both their color and their voice—for example, the blackbird in place of black becomes yellow, and it has another voice; for in summer it sings, while in winter it chatters and makes a racket. The thrush also changes color; for in winter its neck parts are speckled, but in summer they become variegated; however, it does not change its voice at all.

The nightingale sings continuously for fifteen days and nights when the mountains are already covered in vegetation; after that it sings, but no longer continuously. As summer advances, it emits another voiced sound, no longer varied or rapid and flexible, but simple, and changes its color; in Italy, indeed, it is called by another name in this season. It is not seen for long; for it goes into hiding.

The redbreast and the so-called redstart both change into each other; the redbreast is a winter bird, the redstart a summer bird; they differ from each other in (one might almost say) no respect except color. It is the same way with the beccafico and the blackcap; for these too change into each other. The beccafico appears around the fruit season, the blackcap immediately after the fall. These too differ from each other in no respect except color and voice. That they are the same bird has already **633^{a}1** been observed in the case of the change in each kind of these, at the time when they have not yet completely changed and are not yet in one or other of the two forms. It is not at all strange if the voices or colors change in these cases, since even the wood pigeon does not coo in winter (except that cases have been observed where, when good weather has followed very wintry weather, it has cooed and amazed experienced people), but when spring has come, then it starts to utter voiced sounds. In general, the birds emit voiced sounds mostly and most often at the time of mating.

The cuckoo also changes its color and does not articulate its voiced sound clearly when it is about to disappear; it disappears with the Dog Star and appears again with spring until the rising of the Dog Star. The bird that some call the *oinanthê* also disappears when Sirius rises and appears as it sets; for it avoids at one time the cold and at the other time the heat.

734. $600^{b}14$.
735. Reading οἱ ἰχθύες.
736. The parrot wrasse ($508^{b}11$–12, $591^{b}22$–23, *PA* $675^{a}3$–5).

The hoopoe too changes its color and its form, as Aeschylus wrote in his poem:

> This bird, the hoopoe, which its own evils oversees,[737]
> [Zeus] has embroidered in different colors, revealing it
> As a daring bird of the rocks in full armor,
> Who, when spring appears, spreads the wing
> Of a white-feathered hawk. For thus he appears in two shapes,
> A young one's and his own, from a single womb.
> But when at new harvest the wheat is threshed,
> A dappled wing will envelop him again.
> But ever in hatred, from these to other places
> He will go, and will in deserted spots and crags reside.[738]

Some of the birds take dust baths, others water baths, and others neither dust nor water baths. All the ones that are not flyers, but stay on the ground, take dust
633b1 baths—for example, the chicken, the partridge, the francolin, the crested lark, and the pheasant. Some of the straight-taloned ones, and all the ones that spend their time near river, marshes, or sea, take water baths. Others take both dust and water baths—for example, the pigeon and the sparrow. But most of the crook-taloned ones do neither.

This, then, is the mode of these.

A special affection of certain of some of the small birds is that they release gas loudly—for example, the turtledoves. Birds of this sort make a violent movement with their fundament at the same time as the sound.

BOOK 10[739]
ON STERILITY

10.1
Causes of Sterility in Women (1)

[As their age increases,] if a man and a woman fail to generate offspring when they have intercourse with each other, the cause sometimes lies in both, sometimes in only one or the other. First, then, in the case of the female, one should observe how

737. Tereus raped Philomela, the sister of his wife, Procne. As a result, he was transformed into a hoopoe, or a hawk, to lament his own evildoings. Aeschylus combines both versions by having the old hoopoe turn into a young hawk.
738. Fr. 297 Nauck.
739. Text: L. Dean-Jones, *Aristotle: Historia Animalium Book X* (Cambridge, 2023). The status of this book is disputed. It does not belong to *HA* and may be (wholly or in part) not by Aristotle, but by a medical doctor. Its opening phrase also concludes 7.12.

matters stand concerning the uterus, in order that, if the cause lies in this, it may receive treatment, but if it does not lie in this, in order that attention may be given to one of the other two causes.

And just as with any other part, it is evident that it is healthy when it completes its own work adequately and is not pained or exhausted after doing its work—for example, an eye [is healthy] when it produces no rheum, sees, and after seeing is neither troubled nor unable to see again. In the same way, the uterus too [is healthy] if it does not cause pain, adequately completes the work that belongs to it, and after doing its work is not incapacitated but unwearied.

But it is said that even if the uterus is not in a good state, nonetheless as regards its work it may be in a good and painless state. But then its work is worse when it is in this state, just as an eye is prevented from seeing in an exact way if it is not in a good state as regards all its parts, or if there is a growth in it.

Similarly, a uterus, if it is in a good state as regards its vital place,[740] would cause no harm to its work. Indeed, the uterus that is in a good state must first not be in one place and then in another, but remain in the same position; **634^{a}1** except for coming to be further up without affection and pain, and not being too insensitive when touched. This is not difficult to discern. That the uterus should be like this is evident from the following. For if it does not come near [during intercourse], it will not be capable of drawing in [the semen]; for the place from which it must take it up will be too distant from it. But if it remains near and is not capable of going back further up, it will be less responsive, because of always being touched, so that it does not open quickly; but it must do this vigorously and easily. These then are things that must belong to the uterus, and all the uteruses to which they do not belong need some sort of treatment.

Also, the menses must occur correctly, that is, at equal times and not irregularly, when the body is healthy. For when they occur in this way it is a sign that the uterus is in the correct state to open and receive the liquid from the body when the body provides it. But when it releases it too frequently, too infrequently, or irregularly, and the rest of the body is not a contributing cause but is healthy, this must be due to the uterus. For either the uterus does not open at the opportune times because of its insensitivity, so that it receives little, or else it draws in more than it should because of some sort of inflammation in it, so that it gives a sign that it needs treatment, just as the eyes, the bladder, the stomach, and the other parts do. For all places, when they are inflamed, draw in liquid of the sort that is naturally secreted into each place, but not of the same quality or quantity [as when they are healthy]. Likewise, the uterus too, when it yields too much liquid, gives a sign of some inflammatory affection, if the liquid it yields is similar but more abundant.

If, on the other hand, the liquid is dissimilar and more putrefied than that released in healthy women, this is an already present affection and is becoming noticeable. For it is

740. *GA* $766^{a}24$.

necessary for there also to be sorts of pains to give signs that the uterus is not as it should be. In healthy women the whites[741] are released putrefied too, in some when the menses are starting, but in most when they are abating. Those, then, in whom the menses occur more putrefied than in healthy women, or are disordered, are more in need of treatment, since these are impediments to the bearing of offspring. But those in whom the times alone are anomalous and not equal, the affection is less preventive; nonetheless, it gives a clear sign that the state of the uterus is in movement and not always remaining the same. This affection is of a sort to be harmful to women who are naturally well-disposed for conception; nonetheless, it is not a disease, but the sort of affection that settles down even without treatment, unless she presents some other anomaly in addition.

634b1 If the menses change in regularity or in quantity when the rest of the body is not in a constant state, but is sometimes wetter and sometimes drier, the uterus is not at all the cause, but must itself follow along with the state of the body, receiving and releasing [liquid] proportionally. If, on the other hand, it does this while the body is healthy but changing, the uterus itself needs no treatment. But if during an illness [of the body], the uterus either yields too little residue (because the latter is being expended in some other direction where the body is sick), or emits too much (because the body is emptying itself here), this too is not a sign that the uterus itself needs treatment but that the body does. Thus, in women whose menses change together with the states of the body, it is clear that no cause lies in the uterus, since it remains healthy. These women are sometimes weaker, sometimes stronger, sometimes wetter, sometimes drier [than normal]. And the menses in these are more abundant when their body is more bulky, less when it is less so; and if it is wet, the menses are more watery, and if it is dry, more bloody.

The menses start from milk-like whites, which remain odorless; then they turn red, though they are whiter when ceasing. These whites have an odor, not of putrefaction, but more acrid and heavier, but not of pus either. Also, they occur without wasting [of the body],[742] yet along with heating, when the signs[743] occur in this way.

In those women in whom the menses occur in this way, then, matters concerning the uterus are as they should be for the bearing of offspring.

10.2
Causes of Sterility in Women (2)

One must first investigate the menses, to see if they are in the correct state, and after that see how things stand with the mouth of the uterus.[744] For it must be straight; otherwise, the uterus will not draw the seed into itself. For it is in fact into the place in front of the uterus that the woman emits, as is clear when they have wet dreams

741. 581b2.
742. *GA* 738a30–33.
743. I.e., the whites.
744. 510b14–15. I.e., the cervix.

that are complete;[745] for then this place requires treatment by them, since it has become wet, as if during sexual intercourse with a man, because emission on the part of the man is into the same place and not into the interior of the uterus.[746] But when they emit there, it is from there that the uterus draws in the seed with the aid of the breath, like the nose.[747] That is why in fact women become pregnant after intercourse in any position, because in every position, when the uterus is in the correct state, the emission of seed both by them and by the men occurs at the front of it. If it[748] were into it, they would not conceive after intercourse in every position. But if the uterus does not look straight in front of it, but toward the hips, loins, or lower abdomen, it is impossible to conceive due to the cause just mentioned,[749] because it would not be able to take up the seed. If it is fixedly in the latter state either by nature or due to disease, the affection is incurable. But if there is a rupture, either by nature or due to a disease that causes contraction due to inflammation, the affection is one or the other way for the woman.[750]

In those women who are going to be pregnant, the mouth of the uterus must, as was said,[751] be straight and in addition must open correctly. (By "correctly" I mean in such a way that when the menses start, the mouth will be softer to touch than previously and not manifestly dilated.) But if it is in this state, the first signs must be the whites. When the signs are more fleshy in color, it will be evident that the uterus has opened without pain, even if one touches it, and that there is neither unresponsiveness nor any unusual alteration of it. When the menses have ceased, the mouth must be very dilated and dry, though not hard, for a whole day and a half or even two days, which is precisely the state of a healthy mouth. For this, by happening in this way, gives a sign that the uterus is in the correct state and is doing its own work, with its mouth not opening immediately but becoming soft, because the uterus is relaxing at the same time as the rest of the body, not impeding [the menses], emitting first what comes from the mouth itself, and, [only] when the body emits more, opening up. When the signs [of the menses] have ceased, by not closing immediately the uterus gives a sign, if it is looking forward,[752] that it is becoming empty, dry, and thirsty, and that there is nothing left around the passage.

The uterus, then, that has the capacity to draw [the seed] to itself gives a sign that it is in the correct state to conceive after having sex, when it is in this state without pain or insensitivity. And to have no alteration of the mouth is good; for this gives a sign that there is nothing to prevent the uterus from closing up when it should.

10.3
Causes of Sterility in Women (3)

As regards the mouth of the uterus, then, these are the considerations on which the investigation of whether it is or is not as it should be must be based. But as regards the uterus itself, the following sorts of thing should happen after the purgation [of the menses]. First, the woman in her sleep, when she supposes she is having intercourse with a man, she should actually emit easily, as if she were having sex. If it is evident that this happens often, it is better. Also, when she gets up, she should sometimes need treatment of the sort needed when she has had sex with a man, and sometimes she should be dry. This dryness, though, should not continue; but later, after waking, she should become wet, sometimes sooner, sometimes later, even up to half a day, when the day is short.[753] And the wetness must be of the **635b1** sort that occurs when she has had sex with a man. For all these are signs that the uterus is receptive of what is being given, and that the cotyledons have the capacity to draw toward themselves and to be retentive of what they receive, and unwilling to release it.

Further, outbursts of wind should develop in the uterus without affections, as in the stomach, and be released, whether they become large or are small, without disease; for this makes clear that the uterus is no firmer than it should be, nor insensitive either by nature or due to disease, but capable, in keeping with what it receives, of providing room for what grows. In fact, it has elasticity. When this release does not occur, the uterus is either too dense or too insensitive either by nature or due to disease. That is also why it is incapable of nourishing fetuses, but even destroys them. If these states are serious, it will do so when they are still small; if less serious, when they are larger; but if they are altogether mild, it gives birth to inferior offspring, as if nourished in an inferior container.

Further, to the touch, its right and its left parts should be even and its other parts likewise. And during intercourse with a man, it should become wet to an intermediate degree—not often and not exceedingly. This affection is a sort of local sweating, like the saliva that is often produced in the mouth both at the approach of food and when we talk and work too much. And our eyes shed tears when we look at things that are too bright, or due to cold or stronger heat, which these parts master when they can get into a wetter condition. Similarly, the uterus too becomes wet while working, when it can get into a wetter condition. Even a uterus that is most correctly constituted by nature is subject to this affection. That is why women always need treatment, more or less, just as the mouth does from spit. But in some women so much wetness occurs that they are unable to draw up the man's and the woman's emission in a pure state because of its mixing together with the liquid coming from the woman.

753. As in winter.

In addition to these affections, one should observe this much, what happens when a woman believes she has had sex with a man during sleep: what state she is in when she wakes up—for example, whether she is weaker, and if so, always, or sometimes and sometimes not, or sometimes even stronger; and whether she is not drier at first and then becomes wet. For these things should happen in a fertile woman. For the [subsequent] exhaustion[754] is always a sign that the body is emitting seed, and causes the one producing it to become weak; and when it is more corporeal, she becomes weaker. But the fact that they are subject to this without being ill is a sign that this emission is in accord with nature and in the way it should; for otherwise, the weakness would be morbid. And the fact that a woman sometimes even grows stronger, and the uterus is dry, is a sign that the entire body, and that not the uterus alone, is **636^{a}1** receiving [the seed] and hiding it, and that the body is growing strong [from this]. For it is with the aid of breath that the uterus draws in what comes to it from outside, as was said previously.[755] For the woman emits [her seed] not into [the uterus] itself but where the man also does. And everything that is done with the aid of breath is done with strength. So it is clear that the body too[756] of this sort of woman has the capacity to draw to itself.

There are some women who are subject to the sort of affection they call a "wind-pregnancy": they should not, of course, be subject to this affection. The affection is of the following sort. When they have had intercourse with a man, they neither clearly emit seed nor become pregnant, which is why in fact it is called a "wind-pregnancy." The cause of the affection is the uterus, when it is too dry; for having drawn the liquid to itself, it does not emit it outside; instead, the liquid dries up, and when it has become a small thing, it falls out of the uterus, and when it comes out it is unnoticed because of its smallness. When the uterus is very affected in this way and has become excessively dry, it jettisons it quickly, and it soon becomes clear that the woman is not pregnant. But if it does not do this very quickly, she seems in the meantime to be pregnant until it jettisons whatever it is holding in itself. And affections quickly occur in these women that are like affections in correct pregnancies, and if much time passes, the uterus becomes so swollen that the woman seems to be visibly pregnant, until it falls out. Then it becomes like it was before. They attribute this affection to the daimonic. But it is treatable, unless the woman is by nature such as to be very subject to the affection. It is a sign that women are like this if they appear not to emit [the seed] when they have received it from the man and do not become pregnant.

754. 636^{b}28.
755. 634^{b}33–35.
756. I.e., as well as the uterus.

10.4
Causes of Sterility in Women (4)

The uterus is also impeded if it has spasm. Spasms develop in the uterus either when the uterus is being distended by inflammation, or when during childbirth a large quantity of what fills it has suddenly pressed down and the mouth does not open; then, due to the distension, spasm occurs. A sign of its not having spasm is if the uterus is seen not to become inflamed in its works; for if it had spasm, it would be inflamed at that time.

Further, if there is a growth on the mouth [of the uterus] or the mouth is much ulcerated, this impedes conception. It is a sign that it does not have these things if the uterus is seen to open and close in the right way when the menses occur or there is intimacy with a man.

Further, it is the case for some women that the mouth is somehow grown together, in some from birth, in others due to disease. This occurs both curably and incurably. It is not difficult to recognize this, if it is present; for the uterus can neither receive nor emit what it should. If, then, it is seen both to receive from the man and to emit, it is clear that it is not subject to the affection.

Women in whom none of these things is an impediment, but are in the state we said they should be in, if it is not the case that the man is the cause of their childlessness, or that both are capable of producing children but cannot keep even with each other in emitting at the same time but are very discordant—these women will have children. In order to know if the causes [of sterility] lie on the man's side, though there are various signs to get hold of, it would especially be evident more easily if he has sex with other women and generates offspring.

And by not keeping pace with each other [in emitting], even when all the conditions mentioned[757] have been met, they do not generate; for it is clear that this alone is the cause. For if indeed the woman also contributes to the seed and the generation, it is clear that there must be an equal pace kept on both sides. If, then, the man has produced it quickly while the woman has scarcely done so at all (for in most things women are slower), this is an impediment. That is also why, when coupled, they do not generate offspring with each other, although they do generate when they meet with those who keep an equal pace as regards intercourse. For if the woman is excited, prepared, and has the appropriate thoughts, while the man was distressed beforehand and has cooled down, then it is necessary for them to find an equal pace with each other.

10.5
Causes of Sterility in Men

Further, it sometimes happens both to women who have had wet dreams and men who have had sexual intercourse that they are more vigorous, not in strength but

757. 10.1–4.

in health. This occurs when a large quantity of seed has gathered in the place from which it is emitted. If it departs at that time, then, the women are not weakened at all; for they are not always exhausted when it has departed, when what remains behind is sufficient, nor would they be if what has departed is useless. At the same time, they are more at ease, as being set free from overfullness.[758] That is why they become more vigorous, not through strength but through lightness. But when the emission comes out of the amount the body needs, then it makes them weaker. But it soon ceases to do so if the woman is otherwise healthy in body and at an age that produces seed quickly; for seed is among the things that quickly increase and that are capable of increase.[759] And it is especially then that they do not notice that they have become pregnant. For they do not think they have conceived if they do not perceive that they are emitting, though they are in fact emitting, supposing that the emissions from both partners should occur at the same time, both from the woman and from the man.

It is most unnoticed, though, in those women who think that it is impossible to conceive unless they have become dry and what they have been given [by the man] has noticeably been absorbed. But it happens sometimes that both she and the man emit more than she can absorb and is enough [for conception]. When, then, the uterus has drawn in enough, but a great quantity has been left behind, then they do not notice that they have become pregnant. The fact that this sort of thing can happen and that the affection[760] does not come about from all [the seed emitted] is made clear by those animals that generate several offspring from one mating, and by the generation of twins, when they come from one [mating]. For it is clear that one offspring does not come about from all the seed, but that a particular place received a particular part of it, and that what was left behind was a multiple of it.

Further, if several offspring come to be from one mating, which is precisely what is seen to occur in the case of pigs and sometimes in the case of [human] twins, it is clear that the seed comes from all of the body, but was divided into parts in the case of each form;[761] for it is possible for some to be separated off from all, and for all to be separated into many. And so it is impossible at the same time for it to be separated off part by part.

Further, the woman emits into the place in front of the mouth of the uterus, where the man emits too, when she has sex.[762] For from there she draws the seed in with the aid of the breath, just as in the case of the mouth or the nostrils. For everything that is drawn toward something not with the aid of instruments is either of a nature to be drawn upward or else, being light, is drawn from that place with the

758. *GA* 725^{a}3–11, ^{b}5–18.
759. I.e., they do not reach a natural limit of growth or increase and then stop.
760. Pregnancy.
761. Since in identical twins or offspring both the overall form and its parts (the eyes, the nose, and so on) are identical.
762. *HA* 750^{b}34–751^{a}1.

aid of breath. That is why they take care that this place become as dry as it was before emission took place. The route through which the seed goes is naturally constituted as follows in women. They have a tube, just as men also have a sex organ, but within the body. They let out breath through this via a small duct[763] that is placed higher than the one through which women urinate. And that is why, when they are sexually excited, this place[764] is not in the same state as before the excitement. It is from this tube that emission occurs, and the place in front of the uterus is much larger than the part through which the emission falls into that place. This part is, in this respect, like the nose; for the nose too has inside a duct to the larynx and to the outside air. In the same way, that tube has on the outside a small duct that is very small and narrow, just large enough to let the breath out, while the one to the place in front of the uterus is roomy and wide, just as the nose has the duct to the air larger than the one to the mouth and larynx. Similarly, women have the duct to the front of the uterus larger and roomier than the one to the outside.[765]

What is contributed into this[766] [by the woman] produces the same affections,[767] because the woman too emits a fertile seed. And so it follows that these[768] are the same [sorts of] causes. For to those people to whom [the woman's contribution] also seems to be the cause of something else, either disease or death, are not getting a theoretical grasp on the last thing, as far as regards the starting-points, which is what they must see. For in some cases all the causes are the same, in some none are, and in others some are and some are not. They produce effects, then, that are also in proportion. And so in some cases [the woman and the man] go through all the same affections; in others, in which many causes are the same, they go through many; in others they go through few; and in others, in which no causes are the same, they go though none.

10.6
Female Seed; Wind-Eggs

[Female] animals make it evident when they need to be mated. For they pursue the males—for example, the hens pursue and crouch under the male themselves, if he is not excited. Other animals do this too. If, then, the same affections are evident in all animals as regards sexual intercourse, it is clear that the same causes are occurring. But the female bird, at any rate, has an appetite not only to receive something, but also to emit something. There is a sign of this; for if a male is not present, she throws

763. Apparently thought to be in the nose-like clitoral hood.
764. The clitoral glans.
765. Omitting the subtitle.
766. I.e., the mixture in the place in front of the uterus.
767. Rejecting the addition of τὸ αἴτιον.
768. The woman's and the man's contributions.

herself down under another female, becomes pregnant, and lays wind-eggs, since she has an appetite to emit then too, in the way she emits when she in fact has intercourse with the male. Other animals do this too: for a woman once put to the test some female singing crickets she was rearing, having caught them while they were still young, and [when they had grown], they became pregnant spontaneously. From these cases, then, it is clear that every female contributes to the seed—at any rate, if in fact this is seen to occur in the case of one kind [of animal]. For there is no difference between the wind-egg and that [spontaneous] one, except that the wind-egg does not generate an animal. And this is because it does not come from both parents. That is why it is also evident that the male contributions are not all fertile, but some are infertile, when what comes from both is not harmonized as it should be.

Further, women have wet dreams and are subject to the same affections after the wet dreams as when they have had intercourse with a man: relaxation and incapacity.[769] Therefore, if it is clear that they visibly emit during wet dreams, they also contribute at that [other] time, because after wet dreams it is the same place that becomes wet and they need to give themselves the same treatment as when they have had intercourse with a man. So it is evident that emission of seed must occur from both partners if it is to be fertile.

Women do not emit into the uterus itself, but outside, where the man too emits; then from there it draws it into itself. Among females, though, some generate from themselves, as female birds do wind-eggs, while others generate nothing—for example, horses and sheep. Is this because the female bird emits into the uterus, and there is no place outside into which either she or the male emits? That is why, if he does not succeed in mating, [his seed] spills on the ground. But in the four-footed animals there is another place outside into which both the female and the male emit.

The precise thing that in the other animals is mixed with other liquids and is not composed in the uterus because it does not enter it, this is what, in the birds, the uterus receives, concocts, and turns into a sort of body, which in other respects is like an animate being, but is not one, because an animate being must come from both partners. **638^{a}1**

10.7
Molar Pregnancies

But there is a possible objection as to whether women are telling the truth when they say that when they have a wet dream, they wake up dry. For it is clear that the uterus draws in [the seed] upward; so, then, why is it that females themselves do not generate by themselves, if indeed they in fact draw up the male seed when it is mixed

769. 635^{b}31–41.

with theirs? Why do they not also draw up their own seed unmixed, when it reaches the place outside?

In women who have been pregnant for many years the following affection occurs. They give birth to what they call a "mole,"[770] as happened to a certain woman. When she had had intercourse with a man and believed she had conceived, her uterus grew in bulk and at first everything else occurred as expected. But when the time came for giving birth, she neither gave birth nor did the bulk become less; instead, she continued in that state for three or four years, until having contracted dysentery and become dangerously ill, she gave birth to a good-sized mass of flesh, which they call a "mole." In some women, the affection even persists until they grow old and die.

Or is this affection due to heat, when the uterus happens to be hot and dry, and because of this is capable of drawing [the female seed] into itself in such a way that it is able to take it up and keep it in itself? For when the uterus is in this state, if there is no mixture of seed from both partners and it instead receives seed from one of the two, as in the case of the wind-egg, then a so-called mole occurs, which is neither an animal, because it has not come from both, nor inanimate, because what was received was animate,[771] like the wind-eggs. And the mole remains within for a long time because of the state of the uterus and because the case of the bird is different: it lays many eggs internally, when the uterus is distended by them, they are pushed forward and laid, and once the uterus is opened, even the last egg comes out. For there is nothing to impede them, but in fact the body, having a tendency to emit at the time it has been filled up, can no longer make the uterus retractive. But in the case of all the live-bearing animals—because, as the fetus is growing, its capacity changes and it needs distinct nourishment at distinct times—the uterus, when it becomes somewhat inflamed, causes its birth at the right time. But the mass of flesh, because it is not an animal, is alike at all times. For what burdens the uterus need do nothing to make it inflamed. Thus in some women, at any rate, the affection persists even until death, unless as the result of some lucky ailment, as in the case of the woman seized by dysentery.

638[b]1 But does the affection occur because of heat, as was said,[772] or is it rather because of liquid,[773] when the uterus is not so cold as to emit it nor so hot as to concoct it? And that is why the affection lasts a long time, just as things remain boiling for a long time. But boiled things have a limit to their thickening. But uteruses of this sort, being the most extreme cases, make the time long. Further, since the mass of flesh is not an animal, because it is not moving, it does not produce the pain of labor; for the movement of the ligaments is labor, which, because the fetus is alive, expels the

770. *GA* 4.7.

772. 638[a]18.

773. Secluding ὅτι καὶ ἔστι τὸ πλήρωμα οἷον μύει ("because it is in fact the fullness that closes the mouth").

fetus. Also, the hardness of the thing that occurs is a product of parboiling.[774] For it becomes so hard that they cannot cut it with an axe. But some things that have been boiled and all things that have been concocted become soft, but things that are parboiled are unconcocted and hard.

Many doctors, being ignorant of this, say that the affection is moles due to a similarity, if they have merely seen the stomachs swelling up, without edema, and the cessation of the menses, when the affection is prolonged. But it is not; for moles occur rarely. Sometimes a confluence occurs of cold, wet, and watery residues, sometimes of more solid ones, into the place around the stomach, if the women are of this sort in nature or in state. For these produce neither pain nor heat, because of their coldness. And as they increase, some to a greater extent, others to a lesser one, they bring on no other ailment beyond themselves, but rather, like some deformity, remain quiet. The cessation of the menses occurs due to the fact that the residues are used up here, just as when the women are suckling; for in these too the menses either do not occur or occur in small quantities. Sometimes too a confluence from the flesh into the place between the uterus and the stomach seems to be a mole, though it is not.

It is not difficult to recognize if there is a mole by touching the uterus. For if the uterus is compact and has not increased in size, it is clear that the affection is not in it. But if it is like when it contains a child, it has a mole. It will be both hot and dry, because the liquids have been diverted inward, and, as for its mouth, it will be as it is when women are pregnant. But if the mass is something else, the uterus will be cold to the touch and not dry, and the mouth will be as it always is.

ON THE PARTS OF ANIMALS*

BOOK 1

1.1
The Method of Inquiry of Natural Science (1)

Regarding every sort of theoretical investigation and every methodical inquiry, the more humble and more estimable alike, there appear to be two ways for the state to **639a1** be, one that may be well described as scientific knowledge of the subject matter, the other a certain sort of educatedness. For it is characteristic of a well-educated person to be able to judge accurately what is well said and what is not by the speaker. For we 5 consider someone who is well educated about the whole of things to be a person of this sort, and we think that being well educated consists in having the capacity to do what was just stated. Except that in one case, we consider a single individual to have the capacity to judge about (one might almost say) all things, in the other case, about a definite nature; for there might be another person with the same capacity as the one 10 we have been discussing but about a part. So it is clear in the case of inquiry about nature too that there must be certain defining marks by reference to which we can appraise the way of proving things, separately from the question of what the truth is, whether thus or otherwise.

I mean, for example, must one take each substance singly and, where it is con- 15 cerned, define it by itself (for example, where the nature of a human is concerned, or of a lion, or in fact of any other sort of animal, discussing it by itself), or must one posit, in accord with something common, the affections common to all? For many of the same things belong to many sorts of animals that are distinct from each other— for example, sleep, respiration, growth, withering, death, and in addition any remain- 20 ing affections and dispositions of this sort; for at the moment it is possible [only] to speak unclearly and indefinitely about them. But it is evident, especially in speaking with respect to a part, that we will repeatedly say the same things about many kinds; for even to horses, dogs, and human beings each of the ones just mentioned belongs. 25 So if one speaks of the affections with respect to a particular sort, it will be necessary to speak repeatedly about the same ones, whenever the same ones belong to different forms of animals, while they themselves exhibit no difference.

* Translated by C. D. C. Reeve. Text: P. Louis, *Les Parties des Animaux* (Paris, 1957), in consultation with J. Lennox, *On the Parts of Animals* (Oxford, 2001).

But presumably there are other affections that are designated by the same predicate, but differ due to a difference in the form—for example, the progression of animals; for it is evident that it is not one in form; for flying, swimming, walking, and crawling differ. That is why the way one must investigate should not be overlooked—I mean whether one must observe what is common with respect to kind first, and then later the special affections, or [what is common] with respect to the particular [form] from the outset. For as things stand this has not been determined, nor indeed has what will now be stated, whether just as the mathematicians prove the things that astronomy is concerned with, so in that way too the natural scientist, having first observed the things that appear to be so concerning the animals and the parts of each, must then state the why, that is, the cause, or else proceed in some other way.

In addition to this, since we see several causes where natural coming to be is concerned—for example, both the for-the-sake-of-which and the one from which comes the starting-point of movement, it must be determined also about these, which sort is naturally first, which second. It is evident that first is the one we call a for-the-sake-of-which; for this is an account, and the account is a starting-point alike both in the things composed in accord with craft and in those composed by nature. For once the doctor has defined health and the builder has defined a house, whether by thought or by perception, they give the accounts and the causes of each of the things they produce, and why they must be produced in this way. Yet the for-the-sake-of-which and the good are present more in the works of nature than in those of craft.

But though what is of necessity is not present in all the things that are in accord with nature in the same way, pretty much everyone tries to bring their accounts back to it, without having distinguished in how many ways things are said to be necessary. But what is unconditionally necessary is present in the eternal things, while what is hypothetically necessary is also present in all things that come to be, as it is in the products of craft—for example, a house or anything else of this sort. It is necessary, though, that a certain sort of matter be present if there is to be a house or any other sort of end, and this must come to be and be changed first, then that, and so on continuously up to the end and the thing for the sake of which a given thing comes to be and is. And it is the same way too in things that come to be by nature.

But the mode of demonstration and of necessity is distinct in the case of the natural and the theoretical sciences. (These have been spoken about elsewhere.[1]) For the starting-point in the latter is what is, and in the former, what will be—for example, "since health or the human is such-and-such sort of thing, it is necessary for *this* to be or come to be"; but not, "since *this* is or has come to be, *that* of necessity is or will be." Nor is it possible to link eternally the necessity of this sort of demonstration so as to say, "since *this* is, [it is necessary] that *that* is." (About these things too

1. *Ph.* 2.9, *Met.* 5.5, 6.1.

determinations have been made elsewhere:[2] what sorts of things necessity is present in, what sorts [necessity] converts in, and due to what cause.)

But neither must we forget to ask whether it is fitting to state, as those who earlier made a theoretical investigation did, in what way each thing has naturally come to be rather than in what way it is. For the one differs in no small way from the other. It seems that one must begin from what we said previously,[3] that first one must grasp the things that appear to be so about each kind, then state their causes, and then speak about their coming to be; for, in building too these things happen because the form of a house is such-and-such sort of thing rather than the house being such-and-such sort of thing because it comes to be in this way. For coming to be is for the sake of the substance, not the substance for the sake of coming to be.

That is why Empedocles did not speak correctly when he said[4] that many things are present in animals because of the way things happened during the coming to be—for example, that the spinal column is such as it is because it happened to be broken when the animal was bent [in the uterus]. He ignores, first, that the seed that composes it must be present having this sort of capacity, and, second, that its producer must be present prior to it, not only in account but also in time; for it is the human being that generates a human being. So it is because of *that* first one's being such-and-such sort of thing that the coming to be is of such-and-such sort for *this* second one. It is likewise in the case of things that seem to come to be spontaneously as in the case of products of craft; for in some cases things that come to be spontaneously also do so due to craft—for example, health. In the case of the products of craft, of course, something similar to them that is capable of producing them preexists—for example, the craft of sculpting; for a statue does not come to be spontaneously. And the craft is the account of the work that is without the matter. And it is likewise with the things that are due to luck;[5] for as the craft has it, so they come to be.

That is why one must most of all say that since this is the essence of a human, because of this it has these things; for it is not possible for it to be without these parts. Otherwise, one must say the closest thing to it, either in general that it is impossible to be another way or that it is good to be this way. And these things follow. And since it is of this sort, it is necessary for its coming to be to happen in this way and be of this sort. That is why of the parts *this* one comes to be first, then *that* one.[6] And [one must proceed] in this way, then, likewise in the case of all the things composed by nature.

Now, the ancients who first philosophized about nature investigated the material starting-point and this sort of cause, what it is, what sort of thing it is, how the whole comes to be from it, what moves it (for example, strife, love, understanding, or chance), and what sort of nature the underlying matter has of necessity (for example,

2. *APo*. $95^{b}36$–$96^{a}8$, *GC* $337^{b}25$–$338^{a}11$.
3. $639^{b}8$–10.
4. B97 DK.
5. Reading καὶ τοῖς ἀπὸ τύχης ὁμοίως.
6. *GA* $743^{b}18$–32.

that of fire hot, of earth cold, and that of fire light, that of earth heavy). For in this way too they generate the cosmos. And they speak in a similar way about the coming to be both of plants and of animals—for example, saying that as water flowed into the body a stomach and every part that receives nourishment and residue came to be, and that as the breath was passing through the nostrils were torn open.

And air and water are matter for the bodies; for it is from these sorts of bodies that all of them compose the nature. But if human beings, animals, and their parts exist by nature, one must speak about flesh, bone, blood, and all of the uniform parts. Similarly, in the case of the non-uniform parts (for example, face, hand, foot), one must say in virtue of what each of them is the sort of thing it is, and with respect to what sort of capacity. For it is not enough to say what things they are composed of (for example, of fire or earth); [instead,] just as if we were speaking about a bed or anything else of this sort, we must try to define the form of it rather than the matter (for example, the bronze or the wood). But if not, then, at any rate, the matter of the compound; for a bed is a *this in this* or a *this such-and-such sort of thing*, so that one must speak of its configuration as well, and what its visible form is. For nature in accord with shape [or form] is more strictly [nature] than material nature is.

If it is by its configuration and by its color that each of the animals and its parts is what it is, Democritus might be speaking correctly; for he appears to suppose this. At any rate, he says that it is clear to everyone what sort of thing a human is with reference to its shape, on the supposition that it is known by its configuration and color. And yet though the configuration of a corpse has the same shape, nonetheless it is not a human. Further, it is impossible for something in any and every condition (for example, made of bronze or wood) to be a hand, except homonymously, like a doctor in a drawing. For such a hand will not be capable of doing its work, any more than either stone pipes or a doctor in a drawing. Similarly, none of the parts of a corpse is any longer the sort of thing it is—I mean, for example, an eye or a hand.

Democritus, then, has spoken in too simple a way, and in the same way as a carpenter might speak of a wooden hand. This is also the way, indeed, that the natural scientists speak of the processes of coming to be and the causes of configuration (for [ask them] from what capacities things are crafted, and perhaps the carpenter says an axe or an auger, while the natural scientists say air or earth), except that what the carpenter says is better; in fact, it will not be enough for him to say just this much, that when his instrument fell, in one case a hollow was produced, in another a plane surface; instead, by saying why he struck the blow in this way, and for the sake of what (in order that such-and-such sort, or such-and-such other sort, of shape might be produced), he will state the cause.

It is clear, therefore, that the natural scientists do not speak correctly, and that one must state that the animal is of *this* sort, and where each of its parts are concerned, say what it is and what sort of thing it is, just as where the form of the bed is concerned. If, then, this thing is soul, a part of soul, or not without soul (when the soul has departed, at least, there is no longer an animal, nor do any of the parts

remain the same, except in configuration, like the mythological ones that are turned to stone)—if these things are so, then it will belong to the natural scientist to speak and know about the soul (and if not about all of it, about this part by itself in virtue of which the animal is the sort of thing it is), that is, what the soul (or this part by itself) is, and about the coincidental affections it has in virtue of the sort of substance it has, especially as a thing's nature is said of it in two ways and *is* in two ways, one as matter, the other as substance. And nature as substance is nature both as the mover and as the end. And this sort of thing in the case of the animal is the soul, either all of it or some part of it. So in this way too the person getting a theoretical grasp on nature must speak about the soul more than about the matter, inasmuch as it is more the case that the matter is nature because of the soul than the reverse. For even the wood is a bed or a tripod because it is these things potentially.

Someone might raise a puzzle, in view of what was said just now, as to whether it belongs to natural science to speak about all soul, or about a certain part of it. For if it is about all of it, beyond natural science there is no philosophy left. For understanding is of the intelligible objects. So natural science would be knowledge of all things; for it belongs to the same science to get a theoretical grasp on understanding and on **$641^{b}1$** the intelligible objects, if indeed they are in relation to each other and the theoretical knowledge of things that are in relation to each other is in all cases the same, just as is also the case with perception and perceptible objects. Not all soul, however, is a starting-point of movement, nor are all its parts; rather, of growth it is precisely the part that is also present in plants, of alteration it is the perceptual part, and of spatial movement some other part, and not the one capable of understanding; for spatial movement is present in other animals too, but thought in none. So it is clear that [the natural scientist] must not speak about all soul; for not all soul is a nature, although some part of it—whether one part or several—is.

Further, of the results of abstraction none is an object of theoretical natural science, since nature does everything for the sake of something. For it is evident that, just as the craft is present in the products of craft,[7] so in the things themselves there is a certain other starting-point and cause of this sort, which we have, like the hot and the cold, from the universe. That is why it is more likely that the heaven came to be from a cause of this sort, if it came to be, and is due to a cause of this sort, than the mortal animals. At any rate, what is ordered and what is definite are much more evident in the heavens than around us, while what is variable and as it chanced to be are much more so around what is mortal. Some people, however, say that each of the animals is and came to be by nature, while the heaven, in which no chance or disorder whatever is evident, was composed in that way by luck and chance.[8]

We say "this is for the sake of that" wherever there appears to be some end toward which the movement proceeds if nothing impedes it. So it is evident that there is

7. *Met.* $1070^{b}33$.
8. *Ph.* $196^{a}25$–$^{b}5$.

something of this sort, which is precisely we call a "nature." For surely it is not some random thing that comes to be from each seed, but rather *this* one from *that* one, or a random seed from a random body. Therefore, the seed is a starting-point and is productive of what comes from it. For these things are by nature; certainly, they grow from seed. But surely prior again to it is what the seed is a seed of; for while the seed is [of something] coming to be, the end is the substance. And prior again to both of these is what the seed is from. For the seed is twofold, *from* which and *of* which; for it is a seed both of what it came from (for example, from a horse) and of what will be from it (for example, a mule), although not in the same way, but of each in the way just mentioned. Further, the seed is potentially [something]; and we know how potentiality is related to actuality.

642ᵃ1 There are, therefore, these two causes, the for-the-sake-of-which and the of-necessity. And many things come to be because of necessity. But perhaps someone might be puzzled as to what sort of necessity those who say things are of necessity are speaking about; for of two of the modes distinguished in the studies in philosophy[9] neither can apply. The third, though, does apply, at any rate, to the things that have a coming to be; for we say that nourishment is something that is necessary in accord with neither of these two modes, but because it is not possible to exist without it. But this is so as something hypothetically necessary; for just as since the axe must split things, it is necessary for it to be hard, and if hard, then made of bronze or iron, so too since the body is an instrument (for each of the parts is for the sake of something, and similarly the whole is too), it is therefore necessary for it to be of such-and-such a sort and composed of things of such-and-such sorts, if that is to be so.

It is clear, then, that there are two modes of cause, and that as far as possible one must succeed in stating both, but if not, at any rate, try to do so,[10] and that all those who do not state (one might almost say) nothing about nature; for the nature is more a starting-point than the matter is. Even Empedocles stumbled onto this, led by the truth itself, and is compelled to say that the substance and the nature is the ratio—for example, when he says what bone is;[11] for he does not say that it is some one of the elements, or two, three, or all of them, but rather that it is the ratio of their mixture. It is clear, therefore, that flesh too is the same way, as well as each of the other parts of this sort.

The cause of our predecessors not arriving at this mode is that there was then no essence and defining of the substance. But Democritus touched on this first, not as something necessary to the theoretical investigation of nature, but because he was carried away by the facts. In the time of Socrates, however, [interest in] it grew, but inquiry concerning natural things abated, and philosophers turned instead to useful virtue and political science.

9. *APo*. 94ᵇ36–95ᵃ9, *Met*. 1015ᵃ20–36.
10. Reading εἰ δὲ μή, γε πειρᾶσθαι ποιεῖν, δῆλον.
11. B96, B98 DK, *Met*. 993ᵃ15–18.

One must prove things in the following way, for example, that respiration is for the sake of *this*, while *that* comes to be of necessity because of *these* things. But necessity sometimes signifies "if *that*—the for-the-sake-of-which—is to be, it is necessary for these things to hold," while at other times it signifies that things hold that way by their very nature. For it is necessary for the hot to go out and come in again on meeting resistance, and for the air to flow in. This is immediately necessary. And the beating back of the internal heat in the cooling of the external air is inhalation. **$642^{b}1$**

This, then, is the mode of the methodical inquiry, and it is concerning these, and things of this sort, that one must grasp the causes.

1.2
Dichotomous Division (1)

Some people[12] [try to] grasp the particular [form] by dividing the kind into two differences. But this is in one respect not easy, and in another, impossible. For of some things there will be only one difference, the others being superfluous—for example, footed, two-footed, split-footed; for this difference alone is a controlling one. Otherwise, it is necessary to say the same thing many times. Further, it is fitting not to tear each kind asunder—for example, the birds, putting some in one division and some in another, as we have in the diagrammed divisions;[13] for there the result is that some have been divided off with the aquatic animals, some in another kind. This similarity class, of course, has an established name, "bird," and a distinct one, "fish." Other similarity classes are nameless—for example, the blooded and the bloodless; for there is no established name for either of these. If indeed, then, none of the things that are homogeneous must be torn asunder, division into two will be pointless; for people who divide in this way necessarily separate and tear asunder; for some of the many-footed are among the terrestrial animals, others among the aquatic ones.

1.3
Dichotomous Division (2) versus Correct Division (1)

Further, it is necessary to divide by a privation, and those who dichotomize do divide by it. But there is no difference of a privation, insofar as it is a privation; for it is impossible for there to be forms of what is not (for example, of footless or wingless), as there are of winged and of footed. But there must be forms of a universal difference; for if this were not so, why would it be universal and not particular? Some differences, though, are universal and have forms—for example, winged (for one

12. Plato uses dichotomous division as a method of definition in the *Statesman* and *Sophist*.
13. A reference, presumably, to a diagram in which the bird kind is shown torn asunder.

wing is unsplit, another split). And footed is the same way, one foot has many splits, another two splits (for example, the cloven-hoofed), another has no splits and is undivided (for example, the solid-hoofed animals). It is difficult, then, to distribute the animals even into differences of this sort, of which there are forms, so that any animal whatever belongs in them and the same animal does not belong in more than one—for example, winged and wingless (for the same animal is both of these—for example, the ant, the glow worm, and certain others). But most difficult of all, or else impossible, is to distribute them into the bloodless ones.[14] For it is necessary for each of the differences to belong to one of the particulars, so that the opposing one does so too. But it is not possible for some single indivisible form of the substance to belong to animals that differ in form; instead, it will always have a difference—for example, bird differs from human being (for their two-footedness is other and different), and even if they are blooded, their blood is different, or blood must be supposed to be no part of their substance. But if this is so, one difference will belong to two [forms of] animals. And if *this* is so, it is clear that it is impossible for a privation to be a difference.

The differences will be equal in number to the indivisible [forms of] animals, on the assumption that both the [forms of] animals and the differences are indivisible, and there is no common difference. But if it is possible for one that is in fact common to be present,[15] though it is indivisible, it is clear that, in accord with the common one, at any rate, animals that are distinct in form are in the same form. So it is necessary, if the differences into which all the indivisible [forms of] animals fall are special, for none of them to be common. Otherwise, distinct [forms] will go into the same difference. But the same indivisible one must not go now into one and now into another difference in the divisions, nor must different ones go in the same one, and all should go into these.[16]

It is evident, therefore, that it is impossible to grasp the indivisible forms by dividing in the way that those people do who divide the animals, or any other kind, into two. For even according to them it is necessary for the ultimate differences to be equal to all the animals that are indivisible in form. For if there is a certain kind of which shades of white are the first differences, and of each of these there are other differences, and in this way on down to the indivisible ones, the final differences will be four, or some other quantity obtained by doubling from one, and the forms too will be that many. And the form is the difference in the matter.[17] For no part of an animal is either without matter or is matter alone; for a body in any and every condition will not be an animal, nor any of its parts, as has often been said.[18]

14. Reading εἰς τὰ ἄναιμα.
15. Reading εἰ δ' ἐνδέχεται ὑπάρχειν καὶ κοινήν.
16. I.e., their own.
17. *Met.* 1024b6–9, 1058a23–25.
18. Most recently at 641a17–21.

Further, one must divide by things in the substance and not in the intrinsic coincidents—for example, if someone were to divide the [geometrical] figures, so that some have angles equal to two right angles, others angles equal to more (for having angles equal to two right angles is for the triangle a sort of coincidental affection).

Further, one must divide by opposites. For opposites are different from each other—for example, whiteness and blackness, straightness and curvature. So if one of the two is a difference, one should divide by its opposite, and not one by swimming and the other by color.

In addition to these, animate beings, at any rate, must not be divided by the works common to the body and the soul—for example, in the divisions mentioned just now, walkers and flyers; for there are certain kinds to which both differences belong and are flyers and wingless, just like the ant kind. Also, [they must not] be divided by wild and tame; for in the same way this would seem to divide forms that are the same. For (one might almost say that) whatever is tame is also wild—for example, the human beings, the horses, the oxen, the Indian dogs, the pigs, the goats, and the sheep), since each of these, if homonymous, has not been divided separately, and if these are one in form, wild and tame cannot be differences.

In general, however, this is the necessary result of dividing any sort of [kind] whatever by a single difference. Instead, one must try to grasp the animals by kinds, in the way already shown by ordinary people, distinguishing a bird kind and a fish kind. And each of these has been defined by many differences, not by dichotomy. For by dichotomy either it is impossible to grasp them at all (for the same one falls into several divisions and contrary ones into the same division), or there will be only one difference, and this one, whether simply or the result of interweaving, will be the final form. If, on the other hand, one does not take the difference of a difference, one will necessarily make the division continuous in the same way that one makes the account one by means of conjunctions. I mean the sort of thing that results in the divisions into the wingless and the winged, and winged into the tame and the wild, or the white and the black; for neither the tame nor the pale is a difference of winged; instead, each is a starting-point of another difference, while here each is coincidental. That is why one must from the outset divide the one [kind] into many [differences], as we say. For in this way too privations will produce a difference, while by dichotomy they will not produce one.

That it is impossible to grasp the particular form by dividing the kind in two, as some people have thought,[19] is also evident from the following. For it is impossible for just one difference to belong to the divided particular [forms], whether one takes simple or interwoven ones. (I say that they are "simple" if they have no difference, for example, split-footed, and "interwoven" if they do have a difference, for example, the multi-split-footed in relation to the split-footed.) For this is what the continuity of the differences that stem from the kind in accord with the division requires, since

30 **$643^{b}1$** 5 10 15 20 25 30

19. $642^{b}5$.

the totality is one thing. But the mode of expression makes it seem that the final one alone is the [one] difference—for example, "multi-split-footed," or "split-footed"—and that "footed" and "many-footed" are superfluous.

644a1 But that it is impossible for there to be many differences of this sort is clear; for by proceeding continuously one arrives at the ultimate difference (although not at the final one that is the form). This is either split-footed alone, if one is dividing the human or the whole complex—for example, if one were to combine footed, two-footed, and split-footed. On the other hand, if the human were split-footed alone, by proceeding in this way one might arrive at this one difference. But as things stand, since this is not so, it is necessary for there to be many differences that are not under one division. Yet there cannot be *many* differences of the same thing under one dichotomous division; instead, one must end with one [difference] in accord with one [division]. So it is impossible for those who divide in two to grasp any of the particular [forms] of animals whatever.

1.4
Correct Division (2)

Someone might be puzzled as to why human beings have not called by one name embracing one kind what encompasses at the same time both the aquatic animals and the flyers. For there are some affections common both to these and to all the other animals. Nonetheless, they are correctly distinguished in this way. For whatever kinds differ by excess and by the more and the less have been yoked together under one kind, while those that are analogous, have been separated. I mean, for example, that bird differs from bird by the more or by excess (for one is long-feathered, another short-feathered), while fishes differ from birds by analogy (for what is feather in the one is scale in the other). But to do this in all cases is not easy; for most animals have the same affections by analogy.

But since it is the ultimate forms that are the substances, and these are undifferentiated with respect to form (for example, Socrates, Coriscus), it is necessary either to state the things that belong universally first, or to say the same thing many times, as has been said.[20] And universals are things that are common; for things that belong to many we say are universal. But there is a puzzle as to which of the two we should study. For insofar as a substance is what is indivisible in form, it would be best, if one could, to get a theoretical grasp separately on the things that are particular and indivisible in form, just as on human; not, however, in the same way on bird too, for this kind has forms, but rather on whichever of the indivisible [forms] of birds it is—for example, the sparrow, the crane, or something of this sort. On the other hand, insofar as it will result in speaking often about the same affection, because it

20. 639a26–29.

belongs in common to more than one [form], in this respect it is somewhat absurd and tedious to speak separately about each one.

Perhaps, then, the correct course is to speak of some affections in common with **644ᵇ1** respect to kinds, wherever the kinds are said of things by human beings in a well-defined way, and have both a single common nature and forms in them that are not too distant—[for example,] bird, fish, and any other there may be that, though nameless, encompasses in a similar way to a kind the forms within it. But wherever they are not of this sort, we should speak of the particular [form]—for example, about human being and any other there may be of this sort.

The kinds have been defined pretty much by the figures of the parts and of the whole body, when they bear a similarity—for example, as things in the kind of the birds do in relation to each other, as well as those in that of the fishes, the soft-bodied animals, and the hard-shelled animals. For the parts of these differ not by analogous similarity, as bone and spine are related in human being and fish, but rather by bodily affections—for example, large small, soft hard, smooth rough, and such—and, in general, by the more and the less.

How, then, the methodical inquiry about nature must be appraised, and in what way the theoretical investigation of these things might proceed methodically and most easily, further, where division is concerned, in what way it is possible by means of it to grasp things in a useful way, and why dichotomy is in some respects impossible and in others empty, has been stated.

Having determined these things, let us speak about what comes next, making the following a starting-point.

1.5
The Method of Inquiry of Natural Science (2)

Among the substances composed by nature, some are incapable of coming to be and incapable of passing away for all eternity, while others participate in coming to be and passing away. But it has happened that where the former are concerned, though they are estimable and divine, our theoretical investigations are less developed (for both about the things on the basis of which one would investigate them and the things about them we long to know, the things evident to perception are altogether few). But where the plants and animals that are capable of passing away are concerned, we are better equipped for knowledge because of living together with them; for many things belonging to each kind can be grasped if one wishes to take sufficient pains. Each of the two has its charms. For even if our contact with the eternal things is small, nonetheless because knowing them is the most estimable, it is more pleasant than knowing all the things around us, just as a random small glimpse of the ones we love is a greater pleasure than seeing many other great things in exact detail. But because of knowing the others more and in greater number they take preeminence **645ª1**

in scientific knowledge. Further, because they are nearer to us and more of our own nature, they provide some compensation in comparison to the philosophy concerned with divine things. But since we went through them by stating what seems to be so to us,[21] it remains to speak about animal nature, if possible, omitting nothing whether less estimable or more estimable.

For even in the theoretical investigation of animals disagreeable to perception, the nature that crafts them nonetheless provides enormous pleasures to those who are capable of knowing the causes and are by nature philosophers. For it would in fact be unreasonable, even absurd, if we enjoyed investigating the likenesses of animals because of at the same time investigating the craft (for example, painting or sculpture) that crafted them, while not loving even more the theoretical investigation of the ones composed by nature—at any rate, when we are capable of seeing their causes distinctly. That is why we must not be childishly disgusted at the investigation of the less estimable animals. For in all natural things there is something wondrous present—as indeed Heraclitus is said to have told those strangers who wished to meet him but stopped as they were approaching on seeing him warming himself at the oven.[22] For he told them to enter confidently, "for there are gods even here."[23] In this way too one must approach inquiry concerning each of the animals without disgust, on the supposition that in each one there is something natural and good. For what is not random but rather for the sake of something is present most of all in the works of nature, and the end for the sake of which each has been composed or has come to be has taken the place of the good.

But if someone has considered the theoretical investigation of the other animals to be without esteem, he must think the same thing about himself as well; for it is impossible to look at what the human kind is composed of—for example, blood, flesh, bones, blood vessels, and other parts of this sort—without considerable disgust. But in the same way as someone discussing the parts or the equipment of anything whatever must be considered as doing so not to produce a record concerning the matter, nor for the sake of it, but rather for the sake of the whole shape [or form] (for example, concerning the house in fact, and not bricks, mortar, and timbers), so where nature is concerned too, one must consider the discussion to be about the composition and the whole substance, but not about those things that do not occur in separation from their substance.

It is necessary, first, in relation to each kind, to divide off the coincidental affections that belong intrinsically to all the animals, and after this to try to divide off their causes. It was also said previously[24] that many things belong in common to many animals, some unconditionally (for example, feet, wings, and scales, and affections of course in the same way as these), some by analogy. I mean "by analogy" that while to

21. Presumably, in *Cael.* and in (especially) *Met.* 12.

23. 22A9 DK.
24. 639a19–22.

some a lung belongs, to others belongs not a lung, but something else instead of it, which is to them what a lung is to those that have one. And to some blood belongs, to others its analog does, having the very same capacity that blood has for the blooded ones. To speak separately about each of the particular [forms], though, as was also said before,[25] will result in saying the same things many times, whenever we speak about all the things that belong to them; and the same ones belong to many. Let these issues, then, be determined in this way.

But since every instrument is for the sake of something, and each of the parts of the body is for the sake of something, and what they are for the sake of is a sort of action, it is evident that the whole body too has been composed for the sake of a sort of total[26] action. For sawing did not come to be for the sake of the saw, but the saw for that of sawing; for sawing is a certain use. So the body too is in a way for the sake of the soul, and the parts for the sake of that among the works for which each has naturally grown. Therefore, one must speak first about the activities—the ones that are common to all, the ones that are so with respect to kind, and the ones that are so with respect to form. I mean by "common" those that belong to all animals, by "with respect to kind," those whose differences in relation to each other we see to [differ] by excess—for example, I speak of birds with respect to kind, of human with respect to form, as too of everything that in accord with its universal account has no difference at all.[27] For some have what is common by analogy, others with respect to kind, others with respect to form.

Wherever actions are for the sake of other actions, then, it is clear that the [parts] they are the actions of are distinguished in the very same way as the actions. Similarly, if some actions are in fact prior to, and the end of, other actions, it will be the same way too with each of the parts, whose actions are these sorts of actions; and, thirdly, things whose existence necessitates the presence of [other things]. By "affections" and "actions" I mean coming to be, growth, mating, waking, sleep, progression, and any other things of this sort that belong to animals. By "parts" I mean nose, eye, and the composite face, each of which is called a "member." And it is the same way too with the other parts.

And about the mode of our methodical inquiry let this much be said. We must now try to state the causes both of the common and of the special affections, starting, in the way we have determined, first with those that are first. **646^{a}1**

BOOK 2

2.1
The Levels of Composition of Animals

Of which and how many parts each of the animals is composed has been made more perspicuous in the inquiries about them;[28] due to what causes each has the mode of them it does must be investigated now, by taking separately and by itself the ones mentioned in the inquiries.

But since there are three compositions, one might put first the one from what some people call the "elements"—namely, earth, air, water, and fire. Still, it is perhaps better to speak of composition from the capacities, and not from absolutely all of them, but as stated previously elsewhere.[29] For wet, dry, hot, and cold are matter[30] for the composite bodies, while the other differences—for example, heaviness and lightness, density and rarity, roughness and smoothness, and the other bodily affections of this sort—follow along with these.

Second is the composition from the first ones of the nature of the uniform parts in the animals—for example, bone, flesh, and other things of this sort.

Third, and last in number, is that of the non-uniform parts—for example, face, hands, and the parts of this sort.

What holds in the case of coming to be is contrary to what holds in the case of the substance; for what is posterior in coming to be is prior in nature, and first in nature is last in coming to be; for a house is not for the sake of bricks and stones, but rather these are for the sake of the house; and the same holds as regards other matter. Not only is it evident from induction that this holds this way, but it is also in accord with reason; for everything that comes to be has its coming to be produced from something to something, that is, from a starting-point to a starting-point, from a starting-point that is the first mover and already possesses a certain nature to a certain shape or another end of this sort; for a human being generates a human being and a plant a plant, from the underlying matter of each. In time, then, it is necessary for the matter and the coming to be to be primary, but in account, it is the substance and the shape of each thing. This would be clear if one were to state the account of coming to be; for the account of house-building includes that of the house, but that of the house does not include that of house-building. And it is the same way in the case of the others too. As a result, the matter of the elements is necessary for the sake of the uniform parts. For these are posterior in coming to be to the elements, and posterior to them are the non-uniform parts; for these already possess their end and

28. Including *HA* 1.

30. *Met*. 1070b12–13.

limit, having received a composition of the third sort, as happens in the case of many things when their comings to be are completed.

From both these parts, then, the animals have been composed; but the uniform parts are for the sake of the non-uniform ones; for of the latter ones there are works and actions—for example, of the eye, the nostril, and the entire face; of the finger, the hand, and the entire arm. And since the actions and the movements present both in whole animals and in the parts of these are multiform, it is necessary for the things they are composed of to have dissimilar capacities; for softness is useful for some, hardness for others, and some must have elasticity, others the capacity to bend. The uniform parts receive the capacities of this sort one by one (for one of them is soft, another hard; one wet, another dry; one viscous, another brittle), but the non-uniform parts receive them many at a time and compounded together with each other; for the capacities useful to the hand for compressing and for grasping are distinct. That is why the instrumental parts have been composed of bones, sinews, flesh, and the other parts of this sort, but not the latter from the former.

As being for the sake of something, then, these parts[31] are, due to this cause,[32] related in the way just mentioned; but since the way in which it is necessary that they are like this is also sought, it is evident that the relationship preexisted of necessity between them in this way. For the non-uniform parts admitted of being composed of the uniform parts, either of many of them or of one—for example, some of the viscera; for they are multiform in configuration, though they are composed of a uniform body, simply speaking. But for the uniform bodies to be composed of the non-uniform ones is impossible; for then the uniform part would be composed of many non-uniform ones.

These, then, are the causes due to which some parts in the animals are simple and uniform, while others are composite and non-uniform. **647^{a}1**

Some of the parts in animals are instrumental, others are perceptual organs, and each of the instrumental parts is non-uniform, as was said previously,[33] while perception is produced in all the uniform parts, because perceptions of any sort whatever are of a sort to be of one kind, and because for each of the perceptible [kinds] there is a perceptual organ receptive of it. But what potentially is undergoes something due to what actually is, so that the former one and latter one are the same in kind.[34] And that is why in the case of hands, face, or any of the parts of this sort, none of the natural scientists attempts to say that one is earth, another water, and another fire; but they do connect each of the perceptual organs to each of the elements, saying that one is air, another fire. And since perception is present in each of the simple parts, it is most of all reasonable for touch, though it occurs in a uniform part, to be produced in the least simple of the perceptual organs; for it most of all seems to be a

31. The non-uniform ones.
32. The for-the-sake-of-which or final cause.
33. 646^{b}14–17.
34. The kind of the perceptions and the perceptual kind are the same.

perception of many kinds of things, and the perceptible object falling under it seems to have many contrarieties, hot and cold, dry and wet, and yet others of this sort; and the perceptual organ for these—flesh and its analog—is the most corporeal of the perceptual organs. Since it is impossible for there to be an animal without perception, because of this too it would seem necessary for animals to have some uniform parts; for perception is found in these, while actions are present in them in virtue of the non-uniform parts.

But since the perceptual capacity, the one of moving the animal, and the nutritive one are in the same part of the body, as was said previously elsewhere,[35] it is necessary for there to be a primary part possessing starting-points of this sort; and insofar as it is receptive of all the perceptible objects, it is necessary to be one of the simple parts, and, insofar as it is capable of causing movement and action, one of the non-uniform ones. That is why in the bloodless animals the analog of the heart, and in the blooded ones the heart, is a part of this sort; for the heart is divisible into uniform parts, just like each of the other viscera, but because of the shape of its configuration, it is non-uniform.

Each of the parts called "viscera" follows along with the heart; for they are composed of the same matter; for the nature of all of these is bloody, because they are situated on blood-vessel-like ducts and their ramifications. Just as, then, with mud from flowing water, the other viscera are like silt from the flow of blood through the blood vessels; while the heart, because it is both the starting-point of the blood vessels and has within itself the primary capacity for crafting blood, is itself composed, as is reasonable, from nourishment of the sort that it receives. Why the viscera are bloody in shape has been stated, then, and why they are in one respect uniform and in another non-uniform.

2.2
The Uniform Parts; the Hot and the Cold

Among the uniform parts in the animals, some are soft and wet, others hard and solid. Those that are wet are either so generally, or up to the point that it is in their nature to be so—for example, blood, serum, fat, suet, marrow, semen, bile, milk (in those that have it), flesh, and the parts analogous to these; for not all the animals are made of these parts, but rather some are made of the analogs of some of them. Others of the uniform parts are dry and solid—for example, bone, spine, sinew, and blood vessel. Also, the division of the uniform parts, in fact, has a difference; for of some the part is synonymous with the whole, of others it is not synonymous—for example, a part of a blood vessel is blood vessel, but a part of a face is in no way a face.

35. E.g., *Somn.* 455b34–456a6, *Juv.* 468b28–469b11.

First, then, for the wet parts and for the dry ones there are many modes of cause. For some of them are the matter of the non-uniform parts (for each of the instrumental parts has been composed from these, from bones, sinews, flesh, and other parts of this sort, some contributing to its substance, some to its working); some of the wet parts are nourishment for the non-uniform parts (for all get their growth from liquid); and some turn out to be residues—for example, the sediment from dry nourishment and, in those with a bladder, from the wet.

Among these parts, the differences in relation to each other are for the sake of the better—for example, those of the other ones and of blood in relation to blood; for one is finer-grained, another coarser-grained, one purer, another more turbid, and further, one colder and another hotter, both in the parts of one animal (for the upper parts in one animal are distinguished from the lower ones by these differences), and in one animal in relation to another. And, in general, some animals are blooded, while others, in place of the blood, have another part of this sort. Coarser-grained and hotter blood are more productive of strength, while finer-grained and colder blood are more capable of perception and understanding. And the same difference is also exhibited by the things that are present as the analog of blood; that is why the bees and other animals of this sort are more practically wise in their nature than many blooded animals, and why, among blooded animals, those having cold and fine-grained blood are more practically wise than their contraries. But those with hot, fine-grained, and pure blood are best; for animals of this sort are at the same time in a good state for both courage and practical wisdom.

That is also why the upper parts differ in this way in relation to the lower ones, and, again, the male in relation to the female, and the right side of the body in relation to the left. Similarly, the other parts too, both the ones of this sort and the non-uniform parts, must be supposed to exhibit the difference, some for the better or worse, some for the works and the substance of each of the animals—for example, of two sorts of animals with eyes, the one sort are hard-eyed, the other wet-eyed; one sort do not have eyelids, the other do have them, for the greater exactness of sight.[36]

That it is necessary to have blood or something with the same nature as it, and what the nature of the blood is, by first making distinctions concerning hot and cold, one must also get a theoretical grasp on the relevant causes. For the nature of many things is referred back to these starting-points, and many people dispute about which sorts of animals and which parts of them are hot and which cold. For some say that the aquatic animals are hotter than the terrestrial ones, saying that the heat of their nature is in equilibrium with the coldness of their place, that the bloodless animals are hotter than the blooded ones, and the females than the males. For example, Parmenides and certain others say that women are hotter than men, on the supposition that it is because of their hotness and abundance of blood that the menses occur, while Empedocles says the contrary; further, some say that blood and bile are hot,

36. $657^{b}29$–$658^{a}10$.

while others say that one or the other of them is cold. If there is so much dispute about the hot and the cold, what must one suppose about the others? For to us these are the most manifest of the things with which perception is concerned.

It seems to be because things are said to be hotter in many ways that these disputes occur; for it seems that each of the parties has *something* to say in saying contrary things. That is why we must not overlook in what way, in the case of the things composed by nature, one should say that some are hot, others cold, some dry, others wet, since it seems evident that these things are pretty much the causes of death and life, and further, of sleeping and waking, prime of life and old age, sickness and health, while it is not the case that roughness and smoothness, heaviness and lightness, and (one might almost say) none of the others of this sort are. And this is reasonably so; for as was said previously elsewhere, the starting-points of the natural elements are these very things: hot, cold, dry, and wet.[37]

Are things said simply, or in many ways, to be hot? [To answer] one must certainly grasp what the work of the hotter is, or, if there are many, how many. In one way, then, something is said to be hotter when what touches it is made hotter by it; in another way what produces greater perception during touching, especially if accompanied by pain. But it seems that this can sometimes be false; for sometimes it is their state that is the cause of the feeling of pain in perceivers. Further, what is more capable of melting the meltable or more capable of burning the combustible is said to be hotter. Further, if the same thing is, in the one case, larger and, in the other, smaller, the larger is said to be hotter than the smaller.[38] In addition to these two, what cools not quickly but slowly is hotter, and what is heated more quickly is hotter in its nature, we say, than what is heated slowly, as we say that one thing is contrary to something because further away from it,[39] and another like it because closer to it.

One thing is said to be hotter than another, then, in at least this many ways, if not in more. But it is impossible for being hotter to belong to the same thing in all these ways. For boiling water heats more [effectively] than flame does, while flame burns and melts the combustible and meltable, but water does not. Further, boiling water is hotter than a small fire, but boiling water cools more quickly and more thoroughly than a small fire; for fire does not become cold,[40] but all water does. Further, boiling water is hotter to the touch than olive oil, but cools and solidifies more quickly. Further, blood is hotter to the touch than water or oil, but solidifies more quickly. Further, stones, iron, and things of this sort heat more slowly than water, but when they have been heated, they burn more.

In addition to these considerations, some things called "hot" have alien heat while some have their own proper heat, and it makes the greatest difference whether the

37. *GC* 2.2.

38. The temperature of the thing remains fixed; its size changes. It contains more heat (is hotter) when it is larger (*GC* 333^a30–34, *Mete.* 379^b2–6, 380^a34–$^b1$, 381^b18).

39. *Met.* 1055^a3–10.

40. Because it is intrinsically hot.

heat belongs in the latter or in the former way; for the former is close to being hot **649a1**
coincidentally, but not intrinsically, just as if one were to say, if someone with a fever
happened to be musical, that the musical person was hotter than the one with the
heat that accompanies health. But if one thing is intrinsically hot and another coinci- 5
dentally hot, what is intrinsically hot cools more slowly, but the coincidentally hot is
often hotter to perception; again, what is intrinsically hot burns more—for example,
flame burns more than boiling water, while boiling water, which is coincidentally 10
hot, is hotter to the touch.

So it is evident that to judge which of two things is hotter is not simple; for in one way this will be hotter, in another that will be. In some cases of this sort, it is not possible either to say simply that something is, or is not, hot; for what turns out to be the underlying subject is not hot, but coupled together with heat, as if someone were 15
to give a name to hot water or hot iron.[41] It is in this way, in fact, that blood is hot. And this makes it evident that in cases of this sort, in which the underlying subject is hot in virtue of being affected, the cold is not a certain nature,[42] but a privation. Maybe even the nature of fire, in certain cases, is something of this sort; for perhaps 20
the underlying subject is smoke or charcoal, of which the former is always hot (for smoke is an exhalation), while charcoal, when extinguished, is cold. Also, olive oil and pine resin can become cold.

Also possessing heat are pretty much all the things that have been burned—for example, cinders, ashes, the excrement of animals, and, among the residues, 25
bile[43]—due to having been burned and some heat having been left behind in them. But pine resin and the fats are hot in another way, by changing quickly into what is actively fire.

The hot seems both to solidify and to melt. In fact, everything that consists of water only the cold solidifies, while all those consisting of earth, fire does; and among 30
hot things, all those that consist more of earth are solidified quickly due to cold and are insoluble, while those that consist more of water are soluble. But determinations about what sorts of things are solidifiable, and due to what causes they are solidified, have been made more perspicuously elsewhere.[44]

The question of what the hot is and of what sort of thing is hotter, since things are said to be hot and hotter in many ways, will not apply in the same way to all things, 35
but it must be determined in addition that this thing in question is intrinsically hot, **649b1**
while that other is often hot coincidentally; further, that this one is hot potentially, that one actively; and this one in this way, by being hotter to the touch, that one by producing flame and fire. And since things are called "hot" in many ways, it will 5
clearly follow that the same account also applies to "cold."

As regards hot and cold and their degrees, let things be determined in this way.

41. *Met.* 1029b1–1030a17.
42. Reading οὐ φύσις τις ἀλλὰ στέρησίς.
43. The latter two by the inner heat of the animal.
44. *Mete.* 4.6–7.

2.3
The Dry and the Wet; Blood

The next task is also to discuss the dry and wet in a way that conforms with what has been said. Things are also said to be these in many ways—for example, some potentially, others actively. For ice and all solidified wet things are said to be actively and coincidentally dry, since they are potentially and intrinsically wet, while earth, ash, and things of this sort are actively and coincidentally wet when they have been mixed with liquid, but intrinsically and potentially they are dry. But when the mixtures have been disaggregated, the parts that are composed of water are liquid and are both actively and potentially wet, while those composed of earth are all dry. And strictly and unconditionally, things are most of all said to be dry in this way. It is the same way too with the others, the wet things: strictly and unconditionally "wet" holds of them in accord with the same account; and it is the same way in the case of hot things and cold ones.

Now that these things have been determined, it is evident that blood is in a way hot, insofar as what it is for it to be blood[45] is concerned (for something is said to be blood exactly as if we were to signify hot water by a certain name), but the underlying subject, what exactly it is that is blood, is not hot; and in one way blood is intrinsically hot and in another way it is not. For heat will belong in its account, just as pale does in that of the pale human being; but insofar as blood is hot in virtue of an affection, it is not intrinsically hot. It is the same way too as regards dry and wet. That is why, in the nature of the things of this sort[46] too, some, like blood, are hot and wet, but when separated solidify and appear cold, while others, like bile, are hot and coarse-grained, but when separated from the nature of their possessors undergo the contrary, becoming cold and liquified; for while blood becomes more dry, yellow bile becomes more liquid. But to participate more and less in these opposites must be posited as belonging to these things.

In what way, then, the nature of blood is hot, in what way cold, and in what way it shares in their contraries has pretty much been stated.

Since it is necessary for everything that grows to get nourishment, and nourishment in every case is from wet and dry, and the concoction and change of these things occurs due to the capacity of the hot, all the animals and plants (even if due to no other cause, but rather due to this one) necessarily have a natural starting-point for heat—and it, like the workings[47] on the nourishment, is shared by numerous parts. For the first evident service [of nourishment] to the animals is effected due to the mouth and the parts within it (in the case of those whose nourishment must be cut up). But this is in no way a cause of concoction, but rather of good concoction; for

45. Reading οἷον ἦν αὐτῷ τὸ αἵματι εἶναι.
46. I.e., those that are hot, dry, or wet.
47. Reading καὶ αὕτη ὥσπερ αἱ ἐργασίαι.

the division of the nourishment into small pieces makes the working on it by the heat easier. At that point, the working of the upper and lower stomach, with the aid of the natural heat, produces the concoction.

Just as the mouth is a duct for nourishment that has not been worked up, and as the part continuous with it that they call the "esophagus," in those animals that have this part, extends into the stomach, so too there must be many other starting-points, through which the body gets all the nourishment—just as from a trough—from the stomach and from the nature of the intestines. For while the plants get their worked-up nourishment from the earth through their roots (which is why, in fact, residues do not occur in plants; for plants use the earth and its heat as a stomach), pretty much all the animals, and the ones that move by walking manifestly, have the cavity of the stomach like an earth within them, from which, just as the plants do by means of their roots, they must by some means get their nourishment, until the end of the continuous process of concoction is attained. For the working of the mouth transmits the nourishment to the stomach, and it is necessary for something else to get it from this, which is precisely what occurs; for the blood vessels extend through the entirety of the mesentery,[48] starting beneath the stomach and extending up to it. These things must be observed with the help of the *Dissections* and the *History of Animals*.[49]

Since there is something that is a receptacle for all nourishment and for the residues that are produced, and the blood vessels are like a container for blood, it is evident that blood is the final nourishment for the blooded animals, and its analog for the bloodless ones. And that is why not getting nourishment diminishes the blood, while getting nourishment increases it, and why, when it is good, the blood is healthy, and when it is bad, the blood is bad. **$650^{b}1$**

That the blood is present for the sake of nourishment in the blooded animals is evident from these considerations and others of this sort. And that is why, in fact, its being touched does not produce perception, any more than any of the other residues. Nor is nourishment like flesh; for its being touched does produce perception. For blood is not continuous with flesh, nor of the same nature as it, but is found lying in the heart and in the blood vessels like in a container.

But the way in which the parts get their growth from the blood, and further, growth in general, are more properly discussed in the *Generation of Animals*[50] and elsewhere.[51] Now, though, let this much be said (for this much is useful), that blood is for the sake of nourishment, that is, nourishment of the parts.

2.4
Blood Fibers; Serum

Some blood has so-called fibers; some does not have them—for example, that of the deer and the roe deer. That is why this sort of blood does not solidify; for the part of the blood that is watery is colder (which is also why it does not solidify), while the part of it that is earthen solidifies when the liquid evaporates; and the fibers are composed of earth.[52]

Some, at any rate, of the animals also have greater subtlety of thought, not because of the coldness of their blood, but rather because of its fine-grainedness and purity; for what is earthen has neither of these affections. For those animals with finer-grained and purer liquid have their perception more easily moved. Because of this, indeed, even some of the bloodless animals have a more comprehending soul than some of the blooded ones, as was said previously[53]—for example, the bee, the ant kind, and any others of this sort that there may be.

The animals that are very watery are more cowardly; for fear cools. Those, then, that have a blend of this sort in the heart are predisposed to this affection; for water is solidified by cold. That, and other things, is why the bloodless animals are more cowardly than the blooded ones, simply speaking, and why, when afraid, they become immobile, release residues, and, in some cases, change color. On the other hand, those that have very fibrous, coarse-grained [blood] are more earthen in their nature, are both spirited in character and excitable because of their spirit. For spirit is productive of heat, and solids that have been heated heat more than liquids do, and the fibers are solid and earthen, so that they become like sparks in the blood, and produce a boiling in the spirited parts. That is why the bulls and the boars are spirited and excitable; for their blood is most fibrous, and that of the bull, indeed, solidifies most quickly of all. But when these fibers are removed, their blood does not solidify; for just as if one were to remove the earth from mud, the water would not solidify, so it is too with blood; for the fibers are earth. But if they are not removed, the blood is solidified, like watery earth is solidified by cold; for the liquid evaporates when the heat is squeezed out by the cold, as was said previously,[54] and watery earth is solidified not by heat, but by being dried by the cold. And in those bodies there is liquid due to the heat that is present in animals.

The nature of blood is a cause of many things, both with regard to the character of the animals and with regard to perception, and reasonably so; for blood is matter for the entire body; for nourishment is matter, and blood is the last nourishment.[55]

52. *Mete*. 384ᵃ26–33.
53. 648ᵃ5–10.
54. 650ᵇ17–18.
55. 650ᵃ34–35.

It makes a great difference, then, whether it is hot or cold, fine-grained or coarse-grained, turbid or pure.

Serum is the part of the blood that is watery, either because it has not yet been concocted or has been destroyed, so that the serum exists, on the one hand, of necessity, and, on the other, for the sake of blood.

2.5
Fat and Suet

Fat and suet[56] differ from each other in accord with the difference of the blood. For each of them is blood, when—though well-concocted and well-nourished—it has been concocted due to good nourishment and has not been used up in the fleshy part of the animals. Their oiliness makes this clear; for among the wet things, oil is a combination of air and fire. That is why none of the bloodless animals has either fat or suet, because they do not even have blood.

Among the blooded animals, the ones with more corporeal[57] blood have more suet. For suet is earthen, which is why it solidifies, just as what is fibrous itself and soups of this sort do; for it contains little water, but a lot of earth. That is why animals without two rows of teeth, but with horns, have suet. It is evident that the nature of these animals is full of this sort of element, since they are horned and have knuckle-bones; for all these parts are dry and earthen in nature. But those with two rows of teeth, no horns, and multi-split feet have fat rather than suet, which neither solidifies nor breaks in pieces when it is dried, because its nature is not earthen.

When these things are present in moderate quantities in the parts of animals, they are beneficial (for they do not impede perception, but are an aid to health and capacity), but when they are excessive in quantity they are destructive and harmful. **$651^{b}1$** For if the entire body were to become fat and suet, it would perish. For something is an animal in virtue of its perceptual part, and it is the flesh and its analog that are capable of perceiving; but the blood, as was said previously,[58] does not have perception, which is why neither fat nor suet does; for they are concocted blood. So, if the entire body were to become of this sort, it would not have any perception at all.

That is also why very fat animals age quickly; for they are blood-deficient, inasmuch as their blood gets used up to make the fat, and those with a blood deficiency are already on the road to passing away. For passing away is a sort of blood deficiency, and what is deficient is affectable by any random cold and heat. And fat animals are more infertile due to the same cause; for what should have gone from the blood to make semen and seed is used up to make fat and suet; for when blood is concocted,

56. *HA* 3.17–18.
57. I.e., more earthen.
58. $650^{b}1–5$; also $656^{b}19–22$.

it becomes these things, so that in these animals either no residue is produced at all, or else little is.

As regards blood, serum, fat, and suet, both what each of them is and due to what sorts of causes has now been stated.

2.6
Marrow

Marrow too is a certain nature of blood, and not, as some people think,[59] a spermatic capacity of the semen. This is clear in the altogether young; for inasmuch as in fetuses the parts are composed, and the nourishment consists, of blood, the marrow in their bones is also bloodlike. But when they grow and are concocted, just as the parts and the viscera change color (for each of the viscera is also excessively bloodlike when animals are still young), in the same way the marrow does too; and among animals with fat, the marrow is oily and like fat, while in those in which it is not like fat, but in which concocted blood becomes suet, it is suety. That is why in those animals with horns and without two rows of teeth the marrow is suety, while in those with two rows of teeth and multi-split feet it is fatty. The marrow of the spinal column, though, is the sort that is least fatty, because it must be continuous and extend through the entire spinal column, which is divided into vertebrae; if it were either oily or suety, it would not be continuous in the same way, but would be either shatterable or wet.

Some of the animals do not have any marrow worth mentioning, these are the ones that have strong and dense bones, like those of the lion; for the bones of this animal, because they have altogether no [visible] trace of it, seem not to have any marrow at all.[60] But since it is necessary for the nature of the bones, or of what is analogous to the bones (for example, fish-spine in aquatic ones), to be present in animals, it is also necessary for marrow to be present in some, when the nourishment from which the bones are produced is enclosed. And that the nourishment for all the parts is blood was said previously.[61]

It is reasonable too that there are marrows that are suety and that are fatty; for it is because of the heat produced by being enclosed by the bones that the blood is concocted, and the intrinsic concoction of blood is suet and fat. Also, in those that have bones that are dense and strong, it is reasonable that in certain ones marrow is not present, while in others little is present; for the nourishment is used up for the bones. In those that have not bones but fish-spine, the spinal column alone has marrow, both because they are by nature blood-deficient, and because the spinal column is the only hollow fish-spine. That is why it is in it that marrow is produced; for it alone has room and it alone, because of its divisions, has need of something to

59. Plato, *Timaeus* 74a, 77d, 86c, 91b.
60. Cf. *HA* 521b11–16.
61. 650b11–13.

bind it together. That is also why the marrow there, as was said,[62] is of another sort altogether; for, because it is produced in place of a ligament, it is viscous and sinewy, in order that it have elasticity.

Why, then, animals with marrow have marrow has been stated; and what marrow is, is evident from these considerations: it is the residue of nourishment from the blood, distributed to bones and fish-spine, when it has been concocted and enclosed.

2.7
The Brain

Pretty much the next thing to talk about is the brain; for to many people the brain too seems to be marrow, even the starting-point of marrow,[63] because of their seeing the continuity of the spinal-column marrow with it. Yet the brain is (one might almost say) entirely the contrary to marrow in its nature; for while the brain is among the coldest parts in the body, the marrow is in nature hot; its oiliness and fattiness make this clear. That is also why the spinal-column marrow is continuous with the brain; for nature always devises, as a protection against the excess of each thing, the constant presence of its contrary, in order that the one equalize the excess of the other.

That marrow is hot is clear from many considerations. The coldness of the brain, on the other hand, is evident to the touch. Further, it is the most bloodless of all the wet parts in the body (indeed, it has no blood at all in it), and the driest. And it is neither a residue nor one of the continuous parts, but has a special nature, and **$652^{b}1$** reasonably so.

That the brain has no continuity with any of the perceptual parts is clear even by looking at it, and yet more so due to its producing no perception at all when touched, any more than touching the blood or the residues of the animals does. Rather, it is present in animals for the preservation of their entire nature. For while some[64] posit in an unrefined way that fire or some other such capacity is the animal's soul, it is perhaps better to say that it is composed in a certain body of this sort.[65] The cause of this is that the hot is the most capable of the bodies in assisting with the works of the soul; for nourishing and causing movement are works of soul, and these things occur most of all in virtue of this capacity. To say that fire is the soul, then, is like saying that the saw or the drill is the carpenter or the craft of carpentry, because the work gets completed when they are near each other. That it is necessary for animals to participate in heat is clear from these considerations.

But since everything needs a counterbalance in order to hit upon the moderate state and the mean (for the mean has the substance and the account, while each of

62. $651^{b}32–36$.
63. Plato, *Timaeus* 73d, 91b.
64. E.g., Heraclitus.
65. I.e., in one that is fiery or hot.

the extremes separately does not have them), due to this cause, against the heart's place and the heat in it, nature has devised the brain, and it is for the sake of this that this part is present in animals, since it has a nature that is a combination of earth and water. And because of this the blooded animals all have a brain, but (one might almost say) none of the others does, except for those that have one by analogy—for example, the octopus; for they all have little heat due to their bloodlessness.

The brain, then, makes the heat and boiling in the heart well blended;[66] and in order that this part too hit upon moderate heat, the blood vessels extend both from the great blood vessel and from the so-called aorta[67] to the membrane around the brain. And to prevent its being damaged by the heat, in place of a few large ones, dense arrays of thin blood vessels encompass it, and in place of turbid,[68] coarse-grained blood, blood that is fine-grained and pure. That is also why the fluxes in bodies come from the head as their starting-point, in all those cases in which the place around the brain is colder than the proportional blend; for when the nourishment is being vaporized upward through the blood vessels, the residue that is being cooled due to the capacity of this place produces fluxes of phlegm and serum. Likening a small thing to a large one, one must take this to happen in a similar way to the generation of rain; for, on being vaporized, the mist is carried by the heat from the earth to the upper place, and when it is in the air above the earth, which is cold, it is composed back into water because of the cooling, and falls back down to earth.[69] But about these things it is fitting to speak in studies concerning the starting-points of diseases, to the extent that it belongs to natural philosophy[70] to speak about them.

It is this part too that produces sleep in the case of the animals that have a brain, while in those without one, it is its analog. For by cooling the flow of blood from the nourishment, or else due to certain other similar causes, it weighs down the [brain's] place (which is why those who are sleepy are heavy-headed) and makes the heat escape downward along with the blood. That is why, when heat gathers in large quantities in the lower place, it produces sleep, and takes away the capacity to be upright from all those animals whose nature is to be upright, and from the others, the capacity to hold their head upright. These things have been spoken about by themselves both in the studies making determinations about perception and those about sleep.[71]

That the brain is a combination of water and earth is made clear by the following fact about it; for when boiled it becomes dry and hard, and the earth material remains when the water has evaporated due to the heat, just as in the case of the boiled mushes from legumes and from other crops—because the greatest part of them is

66. *GA* 744ᵃ26–31.
67. *HA* 513ᵃ20–27.
68. Reading θολεροῦ. See 647ᵇ32.

70. *Met.* 6.1.
71. *Sens.* and *Somn.*

earth—when the mixed-in liquid departs; for these too become altogether hard and earthen.

Among the animals, it is the human being that has the largest brain for its size, and among the human beings, the males have a larger brain than the females; for the place around the heart and the lung is also hottest and fullest of blood. That is also why, alone among the animals, the human being is upright; for, by prevailing, the nature of heat produces growth from the middle in accord with its own spatial movement.[72]

Against a large quantity of heat, then, a large quantity of wetness and coldness is opposed, and because of this abundance, the bone around the head, which some call the "bregma," is the last to solidify, due to the large quantity of time the heat takes to evaporate it. This happens in none of the other blooded animals.

The human being also has many sutures around the head, and the male more than the female, due to the same cause, in order that the place breathe freely, and **$653^{b}1$** all the more so the larger the brain; for if it becomes too dry or too wet it will not do its work, and either will not cool the blood or will solidify it, so that it produces diseases, fits of madness, and deaths; for the heat in the heart and the starting-point is most susceptible of feeling the affections of the other parts of the body and quickly produces a perception of any change or affection in the blood around the brain.

———

As regards the innate liquids produced in the animals, then, pretty much all of them have been spoken about. As regards those produced later, there are the residues of the nourishment, the sediment from both the bladder and the bowel; and besides these, semen and milk, in those that naturally have each of these. But the studies concerning the theoretical investigation of the residues of the nourishment contain the accounts proper to these (stating in which animals they are present, and due to which causes), while those concerning seed and milk are contained in the studies concerning generation[73] (for seed is a starting-point of generation and milk is for the sake of generation).

2.8
Flesh

The other uniform parts must now be investigated: first, flesh, in those animals that have flesh, and in the other animals its analog; for flesh is a starting-point and intrinsic body of the animals. This is clear even from the account; for we define the animal by its possessing perception, and primarily by the primary sort, which is touch, and

72. I.e., upward.
73. *GA* 1.19–23, 2.2–3 (seed), 4.8 (milk).

of it the perceptual organ is a part of this sort,[74] either the primary one, like the eye-
25 jelly is of sight, or it taken together with the medium,[75] as if one were to add to the eye-jelly the transparent in its entirety. In the case of the other perceptual modalities, to do this would both be by nature impossible and contribute nothing to the work; but in the case of the capacity of touch it is necessary; for among the perceptual organs, it alone, or it most of all, is corporeal.

30 It is evident from perception, on the other hand, that all the other uniform parts are for the sake of the flesh, I mean, for example, bone, skin, sinews, blood vessels, and further, hair, and the claw kind, and any other parts of this sort that there may be. For the nature of the bones has been devised—since it is hard—for the sake of preserving something soft in those animals that have bones; and in those that do not
35 have them, its analog—for example, in some fishes, fish-spine, in others cartilage.

Some of the animals have this sort of protection inside, but some of the bloodless
654ᵃ1 ones have it outside, like each of the soft-shelled animals—for example, the crabs and the crayfish kind; and it is the same way for the hard-shelled-animal kind—for example, the ones called "oysters"; for in all these the fleshy part is inside, while the containing and protecting earthen part is outside; for in addition to the protection
5 provided by a container, the shell—in those that, since they are bloodless, have little natural heat—protects the heat being kindled in them, like a sort of cover put around them. The turtle and the freshwater-turtle kind seem to be the same way, though they are of another kind[76] than the former.

The insects[77] and the soft-bodied animals are composed in a contrary way to these,
10 and in an opposite way to each other; for none of them seems to have a distinctly formed bony or earthen part worth mentioning, but while the soft-bodied animals are pretty much entirely fleshy and soft, to prevent their body from being easily
15 destroyed, as fleshy things are, their nature is intermediate between flesh and sinew. For while it is soft, like flesh, it has elasticity, like sinew; and its mode of splitting is that of flesh, dividing not in a straight line but in circles; for this way of splitting would be most useful for strength.

There is also present in these animals an analog of the spines of fishes—for exam-
20 ple, in the cuttlefishes there is a part called the "sepium," and in the calamaries, the one called the "sword." The octopuses, on the other hand, have no part of this sort, because it has a small cavity (the so-called head), while the others have one of considerable length. That is why, for their straightness and inflexibility, nature traced
25 out these parts, just as, among the blooded animals, it traced out bone in some and spine in others.[78]

74. I.e., flesh and its analog.
75. *DA* 2.11.
76. I.e., blooded animals.
77. *HA* 487ᵃ32–34.
78. *GA* 743ᵇ20–25.

As for the insects, they have things in a contrary way both to the soft-bodied and to the blooded animals, as we said.[79] For none of them has a hard part distinguished from the soft one, but rather their entire body is hard; the hardness, though, is of such a sort that, though more fleshy than bone, is more bony and earthen than flesh, to prevent their body from being easily divisible.

2.9
Bone

The nature of the bones and that of the blood vessels are similar. For each of them, having started from one thing, is continuous, and there is no such thing as a bone by itself, but rather it is a part of something as continuous with it or else being in contact with it or being bound to it, in order for nature to use it both as one and continuous and—with an eye to bending—as two and divided. Similarly too, there **$654^{b}1$** is no such thing as a blood vessel by itself, but rather all blood vessels are part of one. And in fact, if any bone were separate, it would not do the work for the sake of which the nature of the bones exists (for it would not be a cause either of bending or of straightening at all, if it were not continuous but had gaps). And further, it would be harmful, like a sort of thorn or sting present in the flesh. And if some blood vessel were separate and not continuous with its starting-point, the blood in it would not be preserved; for the heat from that starting-point prevents the blood from solidifying; it is evident too that separated blood putrefies.

The starting-point of the blood vessels is the heart, but that of the bones, in all animals that have them, is the so-called spinal column, with which the nature of all the other bones is continuous. For the spinal column is what maintains the length and straightness of the animals. And since it is necessary when the animal moves for its body to bend, the spinal column, though it is one thing because of its continuity, is multipartite due to the division of the vertebrae. Extending from the spinal column in the animals that have limbs, and continuous with it, the bones of these limbs are articulated. Insofar as the limbs have a bend, the bones are bound together by sinews and their extremities fit together, since either one is hollow and the other rounded, or both are hollow, enclosing a knucklebone—like a fastener—in the middle, in order that bending and extension occur; for otherwise it would either be entirely impossible for the limbs to make a movement of this sort, or else they would not do it well. Some of them, though, have the starting-point of one like the end-point of the other, and are bound together by sinews. There are also cartilaginous parts in between the parts responsible for bending, like a pad, so that they do not rub against each other.

Around the bones, fastened to them by thin sinewy bonds, it is the fleshy parts that naturally grow, for the sake of which the bone kind exists. For just as those who

79. $654^{a}9$–11.

mold an animal from clay, or some other wet composition, put one of the solid bodies underneath as a support, then mold the clay around it, so in the same way nature has crafted the animal from the fleshy parts. Bones, then, lie underneath the others, the fleshy parts: in those that move by means of a bend, bones are for the sake of this; in those that are immobile, they are for the sake of protection—for example, the ribs enclosing the chest are for the sake of preserving the viscera around the heart. The **655[a]1** region around the stomach is boneless in all animals, in order that nothing prevent the swelling produced of necessity in animals due to the nourishment, and in females due to the growth of the fetuses within them.

In the animals that are live-bearing, both internally and externally,[80] the capacity of their bones is much the same and strong. For all animals of this sort are much larger [bone-wise], so to speak, in comparison to their bodies, than the sort that are not live-bearing. In some places, in fact, there are many large live-bearing animals—for example, in Libya and in the places that are hot and dry. And for those that are large there must be supports that are stronger, larger, and harder—especially for those of them that make greater use of force. That is why the bones of the males are harder than the bones of the females, especially those of the carnivores (for they get their nourishment through fighting), such as those of the lion; for it has bones that are so hard in nature that a fire is kindled when they are struck, just as it is from stones. The dolphin too has not fish-spines but bones; for it is live-bearing.

In those that are blooded but not live-bearing nature causes them to differ by small degrees—for example, in the case of the birds, though they do have bones, they have weaker ones; in the case of the fishes, those that lay eggs have fish-spine; and in the case of the snakes the nature of the bones is like that of fish-spine, except in the very large ones. In these, due to precisely the same things as in the live-bearing animals, for purposes of strength, the skeleton framework must be stronger.

But the so-called selachians are cartilaginous-spined in nature; for it is necessary for their movement to be more fluid, so that the nature of their supports must also be not brittle, but softer, and because the nature has used up all the earthen material for the skin; and the nature cannot distribute the same excess to many places at the same time.

Present in the live-bearing animals too are many bones that are cartilaginous, in all those cases where it is advantageous for the solid part to be soft and mucilaginous because of the surrounding flesh, as happens, for example, in connection with the ears and the nostrils; for brittle things in protruding parts are quickly shattered. The nature of cartilage and that of bone are the same, though they differ by the more and less; that is also why neither grows [back] when it has been cut.

The sorts of cartilage in the terrestrial animals have no marrow, that is, no separated marrow; for when marrow that is separate is mixed into the entire mass, it

80. *HA* 489[b]10–12.

makes the composition of the cartilage soft and mucilaginous.[81] But in the selachians, though the spinal column is cartilaginous, it does have marrow; for in them, it is in place of bone that this part is present. **$655^{b}1$**

To the touch closely allied to the bones are such part as claws, solid and split hooves, horns, and the beaks of birds. The animals have all these parts for the sake of protection; for the wholes composed of and synonymous with their parts—for example, the whole horn or hoof—have been devised with a view to the preservation of each of them.

The nature of the teeth also belongs in this kind, in some cases being present for a single work, the working up of the nourishment, in other cases both for this and for strength—for example, in all those with saw-like teeth or with tusks. Of necessity all these parts are earthen and have a solid nature; for this is the capacity characteristic of a weapon. That is also why all parts of this sort are present more in the four-footed live-bearing animals, because all of them have a more earthen composition than humankind does.

But as regards these parts and the succeeding ones (for example, the skin, the bladder, the membrane, the hair, the feathers, the analogs of these, and any other parts of this sort that there may be), it is necessary to get a theoretical grasp on them later on, at the same time as on the non-uniform parts, and for the sake of what each is present in animals; for it is from their works, as with the latter parts, that it will be necessary to know these too. But since these parts are synonymous with their wholes, they have been taken out of order now, with the uniform parts. The bone and the flesh are starting-points for all these. Further, we have omitted semen and milk in our theoretical investigation of the liquid and uniform parts; for it is to the *Generation of Animals*[82] that the investigation of these more fittingly belongs. The former is a starting-point while the latter is the nourishment of generated beings.

2.10
The Non-uniform Parts

Now we must speak as if once again at the starting-point, starting first with the ones that are primary. For in all the animals that are complete there are two parts that are most necessary, the one by which they receive the nourishment and the one by which they release[83] the residue; for it is impossible to exist or to grow without nourishment.

The plants (for these also live, we say) do not have a place for useless residue; for from the earth they get nourishment that has already been concocted, and in place of this residue, they release their seeds and their fruit. A third part in all living

81. Reading μυξώδη.
82. 1.19–23, 2.2–3 (semen), 4.8 (milk).
83. Reading ἀφιᾶσιν.

things is intermediate between these, the one in which the starting-point of their life is present.

It is the nature of plants, stationary as it is, not to have multiform non-uniform
656ᵃ1 parts; for, for a few actions, the use of a few instruments is enough; that is why it is necessary to observe the visible forms of these by themselves.[84] But the living things that have perception in addition to life are more multiform in appearance, and some
5 of them more so than others, and yet more prolific in it are all those whose nature participates not only in living, but also in living well.

Humankind is like this; for it alone of all the animals well-known to us participates in the divine, or it most of all. So both because of this and because the shape of
10 the external parts of humankind is most well-known, it must be spoken about first. For, to start with, it is in this kind alone that the parts that are present by nature are also in accord with nature, that is, the upper part of it is toward the upper part of the universe; for the human being is the only animal that stands upright.

That it has a fleshless head follows of necessity from what was said about the
15 brain.[85] For it is not the case, as some people say,[86] that if the head were fleshy, the kind would be longer-lived, but it is fleshless, they say, for the sake of good perception; animals perceive by means of the brain, and parts that are very fleshy do not admit perception. Neither of these claims is true; instead, if the place around the
20 brain were very fleshy, it would produce the contrary of that for the sake of which the brain is present in animals (for it would not be able to cool, if it were very warm); and it is not the cause of any of the perceptual modalities, since it, at any rate, is without perception, just like any of the residues. But not finding the cause due to which some
25 of the perceptions are in the head in animals, but seeing that the brain is more special[87] than the other parts, they couple these two things together by means of a deduction.

That the starting-point of the perceptual modalities is the place around the heart was determined previously in the discussions of perception,[88] and also why two of
30 them, touch and taste, manifestly depend on the heart, why, of the three others, that of smell is intermediate between hearing and sight, which are mostly located in the head (because of the nature of their perceptual organs), and why of these, the organ of sight is [located in the head] in all animals. Hearing and smell in the case of the fishes and animals of this sort make what was just said evident; for these hear and
35 smell, though they have in the head no apparent perceptual organ for these perceptibles. And that the organ of sight, in all those animals that have it, is located in the region around the brain is reasonable; for the brain is wet and cold, and the organ
656ᵇ1 of sight is in its nature water; for among transparent things, water is the most easily

84. Since they are unlike the animals in this respect.
85. 2.7.
86. Plato, *Timaeus* 75a–c.
87. Reading ἰδιώτερον.
88. E.g., *Somn.* 455ᵇ34–456ᵃ5, *Juv.* 468ᵇ28–469ᵇ10.

confined.[89] Further, the more exact of the perceptual modalities of necessity become more exact due to the parts that have purer blood; for the movement of the heat in the blood knocks out the activity of the perceptual part.[90] It is due to these causes that these perceptual organs are in the head.

It is not only the front of the head that is fleshless, but also the back, because in all those that have it this part must be as upright as possible; for nothing holding a burden is capable of being upright, but the head would be a thing of this sort if it were covered with flesh. From this too it is clear that the head is not fleshless for the sake of the brain's perception; for the back of the head contains no brain, but is fleshless nonetheless. It is also reasonable that some of the animals have hearing in the region around the head; for the part called "void" is full of air, and the organ of hearing, we say, is of [the nature of] air.[91] From the eyes ducts go to the blood vessels around the brain; and again from the ears in like manner a duct connects to the back of the brain. Nothing bloodless, though, is capable of perception, nor is the blood itself, but rather some of the things composed of this. That is precisely why nothing bloodless in the blooded animals is capable of perception, nor is blood; for it is no part of the animals.[92]

All those with this part have the brain in the front, because the front is directed toward what is perceived, perception stems from the heart, the heart is among the parts in the front, and perceiving occurs by means of the blooded parts, while the cavity in the back [of the head] is empty of blood vessels. The perceptual organs have thus been ordered by nature in a good way, with those for hearing on the middle of the circumference (for one hears not only in a straight line but in all directions), those for sight in front (for one sees in a straight line, movement is in a forward direction, and one must look before one in the direction the movement is toward[93]). That the organ of smell is placed between the eyes is reasonable. For each of the perceptual organs is double because the body is double, one part the right, the other the left. In the case of touch, though, this is not clear; the cause of this is that the primary perceptual organ is not the flesh or a part of that sort but something internal.[94] In the case of the tongue it is less clear [than in the case of eyes and ears], but more so than in the case of touch; for this perceptual modality is like a sort of touch.[95] Nonetheless, it is clear even in the case of the tongue; for it is visibly divided.[96] **657^{a}1**

89. *Sens.* 438^{a}12–19.
90. *GA* 780^{a}7–14.
91. *DA* 419^{b}34–420^{a}6, *Sens.* 438^{b}20.

93. *IA* 705^{b}8–13.
94. *DA* 2.11.
95. *DA* 2.10.
96. Aristotle is presumably thinking of the underside of the human tongue. In snakes the divide is yet more apparent.

But it is in the case of the other perceptual organs that the perceptual modality is most manifestly double; for there are two ears, two eyes, and the capacity of the nostrils is double in nature. Were the capacity of the nostrils situated in another way, that is, separated as the capacity of hearing is, it could not do its work, nor could the part it is in; for this perception, in animals with nostrils, occurs through breathing, and this part is in the middle and in front. That is why nature has brought together the nostrils in the middle of the three perceptual organs, placing them, as it were, on a single line for the movement of breathing.

2.11
The Ears of the Four-Footed Animals

In the other animals[97] the perceptual organs have also been well placed in relation to the special nature of each. For the four-footed animals have their ears detached and above the eyes, or so it would seem. But it is not so. Instead, it appears to be so because these animals are not upright but bent forward. And since they mostly move in this position, it is useful for the ears to be both higher up and movable; for when rotated they better receive sounds from every direction.

2.12
Hearing in Various Animals

The birds have auditory ducts only because of the hardness of their skin and not having hair but rather being feathered. They do not, then, have the sort of matter from which ears are molded.[98] It is also the same way with the four-footed egg-laying hard-scaled animals; for the same account also applies to these. Among the live-bearing animals, the seal also has not ears but auditory ducts, because it is a deformed four-footed animal.[99]

2.13
Eyelids

The human beings, the birds, and both the live-bearing and egg-laying four-footed animals have a protection for the eyes. The live-bearing ones have two eyelids, with which they also blink. The heavy birds[100] and some others close their eyes with the

97. I.e., other than the human being.
98. 654[b]29–32.
99. *HA* 498[a]31–[b]4, *GA* 781[b]22–28.
100. *GA* 749[b]10–25.

lower eyelid, as do the egg-laying four-footed animals. The birds blink with a membrane that comes from the corners of the eyes.

The cause of their having a protection is that the eyes are wet; in order that they see sharply they are this way due to their nature. For if the eyes were hard-skinned, they would be less liable to harm due to things from outside striking against them, but they would not be sharp-sighted. It is for the sake of the good, then, that the skin around the eye-jelly is thin,[101] while the eyelids are for the sake of its preservation. It is also because of this that all these animals blink, especially the human being. They all do so in order, by means of the eyelids, to prevent things from striking against [the eyes] (and this is not from deliberate choice, but rather nature did it), and the human being does so very often because the skin [around the eye-jelly] is very thin. **$657^{b}1$**

The eyelid is included in the skin; that is why in fact neither the eyelid nor the foreskin grow back together—because they are skin without flesh.

All the birds that close their eyes with the lower eyelid, and also the egg-laying four-footed animals, close them in this way because of the hardness of the skin around the head. For among the feathered animals, the heavy ones, because they are non-flyers, have the growth of their feathers diverted into the thickness of their skin. That is also why they close their eyes with the lower eyelid, while the pigeons and birds of this sort do so with both.

The four-footed egg-laying animals have hard scales, which are all harder than hair, so that their skin is also harder than the skin [of those with hair]. The skin around the head, then, is hard in these animals, which is why they do not have an upper eyelid, but the skin below is fleshy, so that the [lower] eyelid can have thinness and elasticity.

The heavy birds blink not with the lower eyelid but with the membrane, because the movement of their eyelid is slow, while blinking must occur quickly; and the membrane is like this. They blink from the corner next to the nostrils because it is better that the nature of the membranes be from one starting-point, and these have a starting-point at the connection to the nostril; and the front is more of a starting-point than the side.

The four-footed egg-laying animals do not blink in the same way [as the birds], because it is not necessary for them to have wet [eye-jelly] and exact vision, since they stay on the ground. But for the birds it is necessary; for they use their vision from afar. That is why, in fact, the crook-taloned birds are sharp-sighted (for they observe their nourishment from above, and that is why, among all the birds, these fly up to the heights), while those that stay on the ground and are non-flyers—for example, chickens and animals of this sort—are not sharp-sighted; for nothing related to their mode of life urgently requires it.

The fishes, the insects, and the hard-skinned animals have differing eyes, but none of them has eyelids. For the hard-skinned ones do not have them at all (for the use

101. *GA* $780^{a}25–36$.

of the eyelid involves the skin working quickly); but in place of this protection, all the hard-skinned animals are hard-eyed, as if seeing through an eyelid that has been attached [to the eye]. But since, because of the eye's hardness, it is necessary for them to see more dully, nature makes movable the eyes of the insects, and yet more so those in the hard-skinned animals (as it does the ears in some of the four-footed animals), so as to see more sharply, by turning toward the light and receiving its gleam.

The fishes are wet-eyed. For, since they do a lot of moving, they must use their vision from far off. In the case of the terrestrial animals, the air is easy to see through; but in the case of the fishes, since water is contrary to sharpness of seeing, but does not contain as many obstacles to vision as air does, because of this, they do not have eyelids (for nature does nothing pointlessly) and are wet-eyed to counteract the coarse-grainedness of the water.

2.14
Eyelashes and Hair

All animals with hair have eyelashes on their eyelids, while none of the birds and the hard-scaled animals do; for they do not have hair. (As regards the Libyan ostrich we will in fact state the cause later;[102] for this animal does have eyelashes.) And among those with hair, only the human beings have eyelashes on both eyelids. For the four-footed animals do not have hair on their underneath parts, but rather on their back parts, while the human beings, on the contrary, have it more on their underneath parts than on their back parts; for it is for the sake of a covering that hair is present in those animals that have it. In the four-footed animals, the back parts have a greater need for a covering, and though their front parts are more estimable, yet they are smooth,[103] because the animals are bent [forward]. But in the human beings, since, because of their upright stance, the front parts and back parts are evenly matched, nature has traced out[104] an aid to the more estimable parts; for it is always a cause of the better from among the possibilities.

That is also why none of the four-footed animals has a lower eyelash, although in some a few hairs grow under the lower eyelid; nor do they have hair in the armpits or the pubic region, as the human beings do. But, in place of these things, some are covered with hair on the entire back part of their body, as the dog kind is, while some have a crested mane, like the horses and the animals of this sort, and others have a mane, like the male lion.

Further, in those with long tails, nature has adorned them too with hair, long in the case of those with a short stump, like the horses, short in the case of those with a long stump, and in accord with the nature of the rest of the body; for everywhere

102. 4.14.
103. Reading ἀλλὰ λεάζει.
104. 654ᵃ24–26.

nature gives what it takes from somewhere else to another part. In those cases where it has made the body very hairy, the parts around the tail are in want of hair, as, for example, in the case of the bears. **$658^{b}1$**

With respect to the head, the human being is the hairiest of the animals, on the one hand, of necessity, due to the wetness of the brain and due to the sutures (for where there is most wetness and heat, it is necessary for the outgrowth to be greatest), on the other hand, for the sake of protection, so that it may provide a covering, protecting against both excessive cold and excessive heat. And since the human brain is the largest and the wettest, it is also most in need of this protection; for what is wettest boils and freezes most easily, while what is in the contrary condition is less easily affected.

But concerning these matters, the digression resulted from their connection with the causes of the eyelashes, due to their kinship with these, so that as regards the rest, mention must be made on the proper occasions.[105]

2.15
Eyebrows

The eyebrows and the eyelashes are both for the sake of protection, the eyebrows for liquids running downward, so that, like eaves, they may protect the eyes from liquids coming from the head, the eyelashes for the sake of [protection against] things striking against the eyes, like the palisades that some people build in front of fortresses. The eyebrows are at the composition-point of bones, and that is why they become bushy in many cases as people age, so that they need to be trimmed. The eyelids, though, are at the limits of small blood vessels; for where the skin comes to an end, the small blood vessels have the limit of their length. So, because the wet secretion coming out is corporeal, unless some work of nature hinders it for another use, it is necessary, also due to a cause of this sort for hair to occur of necessity in these places.

2.16
The Nose

In all the other four-footed live-bearing animals, the organ of smell does not differ in too far a way from one to another, but among all those with elongated jaw-bones, the so-called snout is the part in which the nostrils are present, in accord with the way that is possible, while in the others the nostrils are more separated from the jaws.

105. *HA* $498^{b}10$–$499^{a}12$, *GA* 5.3–5.

The elephant, however, has the most special part of this sort in comparison to the other animals; for both in size and capacity it is extraordinary. For the nostril[106] is that by which it draws—using it just like a hand—both dry and wet nourishment toward its mouth, and, by wrapping it around them, pulls up trees, again using it just like a hand. For the animal is in nature at the same time a frequenter of marshes and terrestrial, so that when it happens to get its nourishment in the water, while it is necessary for it to breathe (since it is a blooded terrestrial animal), and since it is unable to make the change from liquid to dry as quickly as some of the live-bearing blooded animals do (for its size is excessive), it is necessary for it to use the water as it does the land. In the same way, then, as some divers provide themselves with instruments for breathing, in order to remain in the sea for a long time by drawing in air from outside the liquid through the instrument, so nature makes the length of the nostril something of this sort for the elephants. That is why they breathe by lifting their nostril up out of the water whenever they make their journey through liquid; for as we said, the elephant's proboscis is its nostril.[107]

But since it is impossible for there to be a nostril of this sort if it is neither soft nor able to bend (for its length would impede taking in nourishment from outside, just as they say[108] the horns do in the backward-feeding oxen; for they say that these graze by going backward, rump foremost), such a nostril is present in elephants (nature, as is its custom, uses the same parts for many additional purposes) in place of using the front feet. For the many-toed four footed animals have front feet in place of hands, and not only for the sake of supporting their weight. And the elephants are among the many-toed ones, that is, they are neither cloven-hoofed nor solid-hoofed. But since the size and weight of their body are great, because of this their feet are only for the sake of support, and because of their slowness and their natural unfitness for bending, they are useless for anything else.

The elephant has a nostril, then, because of breathing, just as each of the other animals with a lung also does, but because it spends time in what is wet, and its moving out from there is slow, its nostril can be rolled up and is long; but because it has been deprived of the use of its [front] feet, nature, as we said,[109] also uses this part for the aid that would have been produced by the feet.

The birds, the snakes, and the other blooded egg-laying four-footed animals, though they have the ducts of the nostrils in front of the mouth, and so-to-speak nostrils, they do not have any that are manifestly distinct, except in virtue of their work. The bird, at any rate, has no nose at all to speak of. This has come about because in place of jaws it has the so-called beak. The cause of these things is that the nature of the birds was composed in this way. For they are both two-footed and winged, so that it is necessary for their neck and head to have little weight, just as it also is for their chest

106. I.e., the trunk.
107. *HA* 497ᵇ26–30.
108. Herodotus 4.183.
109. 659ᵃ21–29.

to be narrow. In order, then, for it to be useful both for strength and for nourishment, the beak they have is bony, while it is narrow because of the smallness of their head. In the beak they have the ducts for smell, but to have nostrils is impossible.

As regards the other animals, the non-breathing ones, the cause of their not having nostrils was stated previously,[110] but some perceive odors through their gills, others through their pipe,[111] while the insects do so through their diaphragm. And all of them smell, just as they move, by means of their innate breath; for this is present in all by nature and is not brought in from outside.

Below the nostrils is the nature of the lips in those blooded animals that have teeth. In the birds, in fact, as we said,[112] for nourishment and strength, their beak is bony; for it has been brought together into one thing in place of teeth and lips, just as if, having removed the lips from a human being and joined together the upper teeth and the lower teeth separately, one were to elongate their length, making them narrow on both sides; for this would already be a bird-like beak.

In the other animals, the nature of the lips is for the preservation and protection of the teeth, which is why, as their teeth share in what is exact and correct or the contrary, so too they have distinct sorts of lips. The human beings have lips that are soft, fleshy, and able to separate, both for the sake of protecting the teeth, as with the other animals, but yet more so for the good; for these are also used for speech. For just as nature made the human tongue unlike those of the other animals, using it for doing two works (as we say it does in many cases), for the sake of both flavors and speech, it has made the lips both for the sake of speech and for the protection of the teeth. For speech that is by means of the voice is composed of articulate sounds, and if the tongue were not of the sort it is or the lips not wet, most of the articulate sounds could not be uttered; for some involve applications of the tongue, others applications of the lips.[113] But of what sorts these are, how many they are, and what differences they exhibit must be learned from practitioners of the craft of versification.

It follows that it is necessary from the outset for each of these parts to be serviceable for the use mentioned and to have a nature of the sort it does; that is why they are fleshy. But the flesh that is present in the human beings is softest. This is because they are the most perceptive of the animals with respect to perception by means of touch.

2.17
The Tongue

The tongue in animals is under the roof of the mouth, and is pretty much the same in all the terrestrial animals, while in the other animals it is not the same, both

110. $656^{a}33$–37, *HA* $589^{b}13$–22.
111. Reference unclear.
112. $659^{b}10$.
113. *Po.* $1456^{b}25$–31.

compared to each other and compared to the terrestrial animals. The human being has the most detached, softest, and broadest tongue, in order that it be useful for doing both its works: it is useful for the perception of the flavors (for the human being is the sharpest perceiver among the various animals, and his tongue is soft; for it is, tactilely, the most perceptive, and taste is a sort of touch), and his soft and broad tongue is also useful for the articulation of the articulate sounds, that is, for speech; for it is most able to draw in and stick out in all sorts of ways, since it is soft, broad, and detached. This is clear in those in whom it is not very detached; for they speak inarticulately and lisp, and this comes from a want of letters.

In what is broad, the narrow is also included; for the small is present in the great, but not the great in the small. That is why, among the birds, those most able to utter articulate sounds have broader tongues than the others.

The blooded live-bearing four-footed animals have little articulation in their voice; for they have a tongue that is hard, not detached, and thick. Some of the birds, though, have many voices, and the crooked-taloned ones have broader tongues. The smaller ones have many voices. And though all use their tongue to communicate with each other, some do so more than others, so that in some cases they even seem to be learning from each other. These things have been spoken about in the *History of Animals*.[114]

Among the terrestrial egg-laying blooded animals, most have a tongue that is useless for doing the work of the voice, attached and hard as it is; but for the tasting of flavors, the snakes and the lizards have a long divided tongue; the snakes have so long a tongue that it can be extended from small to great, and a divided one, with a thin hair-like tip, because of their gluttonous nature; for it gets a double pleasure from flavors, as if having a double perceptual modality of taste.

Both the bloodless and all the blooded animals have the part capable of perceiving flavors; for even those that seem to most people not to have one, like some of the fishes, in a way have a rudimentary one, and one pretty much the same as in the river crocodiles. But most of these do not appear to have it due to a reasonable cause; for the place of the mouth is spinous in all these animals, and because there is little time for the perception of flavors in the aquatic animals, and as the use of the tongue is slight so too is its articulation. The passage of nourishment to the stomach is quick because they cannot spend time sucking out the juice;[115] for water would get in. So unless one pulls their mouth open, the tongue does not appear to be a separate part. And this place is spinous; for it is composed by the contact of the gills, which have a spinous nature.

In the crocodiles, having an immovable lower jaw also contributes something to the disablement of this part. For their tongue is attached to the lower jaw, and they have the upper and lower jaws, as it were, inverted; for in the other animals it is the

114. 4.9.

115. That embodies flavor.

upper jaw that is immobile. They do not have their tongue attached to the upper jaw, because it would be contrary to the entrance of nourishment, but to the lower one, because it is like the upper one transposed. And further, though it is a terrestrial animal, it lives the life of the fishes, so that because of this too it is necessary for it to have this part unarticulated.

Many of the fishes also have a roof of the mouth that is fleshy, and some of the river fishes have one that is very fleshy and soft, for example, the ones called the "carps," so that, to those who do not investigate in an exact way, they seem to have a tongue there. But the fishes, due to the cause mentioned,[116] do have a tongue, though the articulation of their tongue is not evident. And it is for the sake of the nourishment found in flavors that this tongue-like part contributing to perception exists; but it is not equally perceptive everywhere, but mostly in the tip, which is why in the fishes only this part is separated.

All the animals have an appetite for nourishment, since they have perception of the pleasure that arises from nourishment; for appetite is for pleasure. But the part by which the perception of nourishment is produced is not the same in all: in some it is detached, while in others it is attached, namely, in all the ones in which no work for a voice is present; and in the latter it is hard, while in the former it is soft and fleshy. That is also why in the soft-shelled animals—for example, the crabs and animals of this sort—something of this sort is present inside the mouth, and also in the soft-bodied ones—for example, the cuttlefishes and the octopuses.

Among the insects, some have a part of this sort inside—for example, the ant kind—and, in like manner, many of the hard-shelled animals; others have it outside, like a sting, soft in nature and hollow, so as to taste and draw in nourishment with it at the same time.[117] This is clear in the case of the flies and the bees, and all the animals of this sort, and further, in the case of some of the hard-shelled animals; in fact, in the purpuras this part has so great a capacity that it can pierce the shells of the mussels, like the spiral-shelled ones people use as bait to catch them. Further, the gadflies and the horseflies pierce the skin, in the one case, of the human beings and, in the other, that of the other animals too. In these animals, then, the tongue is of such a nature as to be like a counterpart to the nostril of the elephants; for in the elephants the nostril is for the sake of protection, and in these the tongue takes the place of a sting.

But in the case of the other animals the tongue is altogether as we said.

116. 660^{b}11–14.
117. 678^{b}13–18.

BOOK 3

3.1
The Teeth

Coming next after what has been said is the nature of the teeth in animals, and the mouth that is encompassed by them and composed of them. In animals other [than the human being], the nature of the teeth has a common work, that on the nourishment, and a separate work, that with respect to kinds: in some it is present for the sake of strength, this being divided into that for attack and that for defense; for some animals have teeth for the sake of both, both for defense and for attack—for example, those wild animals that are carnivorous in nature; while others have them for the sake of protection, as many of the wild and the tame animals do.

The human being has teeth naturally well composed for the common use, the front ones sharp in order to cut, the molars broad in order to grind. The canines, which are in nature intermediate between the two,[118] divide these from each other; for the intermediate participates in both extremes, and the canines are in a way sharp and in a way broad. It is the same way too in the case of all the other animals that do not have all their teeth sharp. But it is especially for speech that the human being has these sorts of teeth and this many of them; for the front teeth contribute greatly to the generation of articulate sounds.

Some animals have teeth, as we said,[119] for the sake of nourishment alone. But among all those that have them for protection and also for strength, some have tusks, for example, the pig, while others have sharp interlocking teeth, hence they are called "sawtoothed." For since it is in their teeth that their strength lies, and this is produced due to their sharpness, rows of teeth that are useful for strength fit together one into the other, in order not to get blunted by rubbing against each other. And none of the animals is both sawtoothed and tusked, because nature produces nothing pointless or superfluous; but, for some, protection is by means of striking, for others, by means of biting. That is why female pigs bite; for they do not have tusks.

But one must grasp a universal point, one that will be useful both in the case of these matters and in the case of many of the ones that will be spoken about later. Among the instrumental parts that are for strength and protection, nature gives each of them only or more so to those capable of using them, and mostly to those most capable—for example, a sting, a spur, horns, tusks, and any other part of this sort there may be. And since the male is stronger and more spirited, in some cases he alone has parts of this sort, in others more so. For all those parts that it is necessary for the females too to have—for example, those for nourishment—they do have, though

118. *HA* 501b16–19.
119. 661b1.

they have them less, while those that are for none of the necessities, they do not have. And that is why the males among the deer have horns, while the females do not have them. The horns of the female cows and of the bulls differ too, and likewise with the sheep. Also, while the males have spurs, the majority of the females do not. It is the same way too in the case of the other parts of this sort.

All the fishes are sawtoothed except the one called the "parrot wrasse"; many also have teeth both on their tongue and on the roofs of their mouths. The cause of this is that it is necessary, since they are in liquid, to take in liquid at the same time as nourishment, and to dispatch the liquid quickly. For it is not possible for them to spend time grinding up the nourishment, since the liquid would flow into their stomach. That is why all their teeth are sharp for cutting. Again, they have many of them in many places in order that, in place of grinding up the nourishment, they can cut it into many pieces due to their large number. And they are curved because it is in the teeth that pretty much all their strength is due to them.

The animals also have the nature of the mouth both for the sake of these works, and further, for the sake of breathing, that is, all the ones that breathe and cool themselves from outside. For nature intrinsically, as we said,[120] puts the parts common to all animals to many special uses—for example, in the case of the mouth nourishment is common to all, while strength is special to some and speech to others, and further, breathing is not common to all. But nature has brought all these uses together into one part, producing a difference in this part for the differences in its work. That is why some have narrower mouths, others wider mouths. For all those that are for the sake of nourishment, respiration, and speech are narrower, while among those that are for the sake of protection, all the sawtoothed ones open wide. For since the animal's strength lies in biting, it is useful for the opening of its mouth to be large; for it bites with more teeth over a greater area to the extent that it opens its mouth wider. Among the fishes, the biting and carnivorous ones have a mouth of this sort, while those that are not carnivorous have a tapering one; for a mouth of this sort is useful for them, while the other sort would be useless.

In the birds the so-called beak is their mouth; for they have this in place of lips and teeth. It differs with respect to uses and protections. For the ones called "crook-taloned," because they are carnivorous and eat no seed, all have crooked beaks; for a beak of this sort is naturally useful for mastering prey and better at applying force. But their strength lies both in this part and in their talons; that is why they also have talons that are more crooked.

In each of the other birds the beak is useful for their mode of life—for example, in the woodpeckers it is strong and hard, and in the crows and the crow-like birds, while in the small birds it is thin for collecting seeds and grasping small animals. All those that are herbivores and all those that live around marshes, such as those that are swimmers and web-footed, though some have a beak that is useful in another

120. 659^a21, $^b35$.

way, others are broad-beaked; for by being like this it is able to dig easily, just like, among the four-footed animals, the snout of the pig; for the pig too is a root-eater. Further, the root-eating birds, and some of those with similar modes of life, have the extremities of their beaks serrated; for, since they are herbivores, beaks of this sort make things easier.

———

The other parts of the head, then, have pretty much been spoken about, but, in the human beings, the one that is between the crown of the head and the neck is called the "face (*prosôpon*)," being named after its action, as it seems; for because the human being alone among the animals is upright, it alone sees from afar (*prosôthen opôpe*) and transmits its voice forward (*to prosô*).

3.2
The Horns

The horns must now be spoken about; for these too, in those that have them, are naturally on the head. No non-live-bearing animal has horns. By way of similarity, however, and by extension certain other sorts are also said to have horns; but in none of them is the work of the horn present. For it is for protection and strength that the live-bearing animals have horns, which is not the case for any of the other animals that are said to have horns. For none of them uses their horns either for protection or for mastery, which are precisely the works of strength.

None of the multi-split-footed animals has a horn. The cause of this is that the horn is a cause of protection, while other means of defense are present in the multi-split-footed animals; for to some nature has given claws, to some teeth for fighting, and to others some other part adequate for defense.

Among the cloven-hoofed animals, many have horns for strength, as do some of
663a1 the solid-hoofed ones, while some have them also for protection. But to those that do not have them, nature has given another [sort of] strength for preservation—for example, bodily swiftness, like that given to horses for protection, or size, like that given to camels. For excessive size is also sufficient to prevent destruction by other animals; this is precisely what happens in the case of camels, and yet more so in that of the elephants. The animals with tusks—as, for example, the pig kind—are cloven-hoofed.

To those for which prominent horns are naturally useless, nature has added another means of protection—for example, swiftness to the deer (for their size and their many branches harm more than benefit them), and to the antelope and the gazelle (for against some they stand their ground and defend themselves with their horns, while from those that are savage and pugnacious they flee); and to the bison (for in these the horns are naturally bent toward each other) nature has added the

emission of residue; for with this they defend themselves when frightened.[121] And by means of the same sort of emission other animals also preserve themselves. But nature has not given to the same animals means of protection that are at the same time sufficient and many.

Most of the horned animals are cloven-hoofed, but there is also one said to be solid-hoofed, which they call the "Indian ass." Most of the animals, then, just as they have a body that is divided into two parts by which they produce movement, right and left, also naturally have two horns, due to the same cause. There are also one-horned animals—for example, the oryx and the one called the "Indian ass." But while the oryx is cloven-hoofed, the ass is solid-hoofed.

The one-horned animals have the horn in the middle of the head; for in this way each of its parts can most of all have one horn; for the middle is equally common to both of the extremes. It would seem reasonable for the solid-hoofed animals to be one-horned rather than the cloven-hoofed ones; for hoof and nail have the same nature as horn, so that the division of the hooves and horns occur at the same time and in the same animals. Further, the division—that is, the cloven-hoof—is present in virtue of a deficiency of the nature, so it is reasonable that, in the case of the solid-hoofed animals, nature, since it had provided an excess in the hooves, withdrew it from up above and made them one-horned.

Nature also proceeded correctly in placing the nature of the horns on the head, and not like Aesop's Momus, who greatly blames the bull because it does not have its horns on its shoulders, the place from which it would have produced the strongest blows, but on the weaker part of the head. For Momus was not seeing sharply when **$663^{b}1$** he made this criticism. For just as if horns grew naturally somewhere else on the body, they would supply weight while being otherwise of no use at all and even an impediment to many of its works, they would also be that way if they grew naturally on the shoulders. For not only must one investigate from which place the blows would be stronger, but also from which one they would strike things further away. So, since bulls do not have hands either, and for horns to be on the feet is impossible, and on the knees they would prevent them from bending, it is necessary that they have them just as they now do, on the head. At the same time too, in this way they are naturally the least an impediment for the other movements of the bodies.

The horns are solid throughout only in the deer, and they alone shed them, on the one hand, for benefit of being relieved of a burden, and, on the other, of necessity, because of their weight. The horns of the other animals are hollow up to a certain point, but their extremities are solid because they are useful for striking blows. But in order for not even the hollow part to be weak, the horn grows naturally from the skin, and into it a solid part from the bones is inserted; for in this way the possession of horns is both most useful for strength and least an impediment to the rest of their mode of life.

121. *HA* $630^{b}8$–13.

What the nature of the horns is for the sake of, then, has been stated, and due to what cause some animals have parts of this sort, while others do not; but since there is a necessary nature, we must now say how the nature that is in accord with the account uses the things present of necessity for the sake of something. First, then, what is corporeal and earthen is present in larger quantities in the larger animals, while we know of no horned animal that is altogether small; for the smallest one known is the gazelle. One must, though, get a theoretical grasp on nature by looking to the many; for it is what holds in all cases or for the most part that is in accord with nature. What is bony in the bodies of animals is earthen; that is why, in fact, it is present in the largest quantities in the largest animals, to speak so by having looked at what holds for the most part. At any rate, the residue-like excess of this sort of body, since it is present in the larger ones among the animals, is used by nature for protection and advantage, and its flow is of necessity to the upper place,[122] in some cases assigned to teeth and tusks, in others to horns. That is why none of the horned animals has two rows of teeth; for they do not have upper front teeth; for nature takes away from there and adds to the horns—that is, the nourishment [otherwise] given to these teeth is used up in the growth of the horns.

Female deer do not have horns, but as regards the teeth they are like the males; the cause of this is that they are both of the same nature, that is, horned. But the horns have been taken away from the females because, though they are not useful even to the males, the males, because of their strength, are harmed less by them.

Among the other animals in which a part of the body of this sort is not formed into horns, in some cases nature has increased the size of all of their teeth in common, while in some it has produced tusks, like horns coming from their jaws.[123]

3.3
The Neck and Its Parts

As regards the parts in the head, then, let them be defined in this way, and naturally under the head is the neck, in those animals that have a neck. For not all animals have this part, but only those that have the parts that the neck is naturally for the sake of; these are the larynx and the so-called esophagus.[124]

The larynx is naturally for the sake of the breath; for it is through this that the animals draw in the breath and expel it when inhaling and exhaling. That is why those that do not have a lung do not have a neck either—for example, the fish kind.

122. Because the upper part of the large quadrupeds that have teeth or horn for protection is bent forward (658ᵃ22), the flow of the earthen material to it is actually downward, as is necessary.

123. External parts are returned to in 4.6.

124. *HA* 495ᵃ18–20.

The esophagus is that through which the nourishment proceeds to the stomach; so all those that do not have a neck obviously do not have an esophagus either. But it is not necessary to have the esophagus for the sake of nourishment; for it provides nothing for it. Further, it is possible for the stomach to be placed right next to where the mouth is situated, while for the lung this is not possible. For, since it is bipartite, there must be something common, like a pipe, in virtue of which the breath is divided by way of the windpipes into the bronchial passages; and in this way the lung can best accomplish inhalation and exhalation. And since this instrument having to do with breathing of necessity has length, it is necessary for there to be the esophagus between the mouth and the stomach. The esophagus, for its part, is fleshy, with a sinewy elasticity: sinewy, in order that it have the capacity to stretch when nourishment enters; fleshy, in order to be soft, to be able to yield, and not harmed when it is abraded by the nourishment going down.

The part called the "larynx" and the windpipe are composed of cartilaginous body; for they are not only for the sake of breathing, but also for the sake of voiced sound, and what is going to make a sound must be smooth and hard.[125] The windpipe is situated in front of the esophagus, although this impedes it in the reception of nourishment; for if something either dry or wet slips imperceptibly into the windpipe, it produces choking, distress, and violent coughing. This should surely be a cause of wonderment to any of those who say that it is by means of this part that the animal takes drink; for the things mentioned visibly occur in every case in which some of the nourishment slips in. But, on many grounds, it is manifestly ridiculous to say that animals take in drink in this way. For there is no duct into the stomach coming from the lung like the esophagus we see coming from the mouth. Further, in cases of vomiting and seasickness, it is not unclear where the liquid is visibly flowing from. It is also clear that the liquid is not from the outset collected together in the bladder, but rather beforehand in the stomach; for the sediment of red wine appears to color the residues from the stomach; and it turns out that this is often evident also in cases of wounds to the stomach. But it is perhaps, in fact, foolish to overly examine foolish accounts.

The windpipe by being situated, as we said,[126] in front is given trouble by the nourishment; but for this nature has devised the epiglottis. Not all the live-bearing animals have this part, but rather all the ones that have a lung and their skin hairy, and that are naturally neither hard-scaled nor feathered. In those that are hard-scaled or feathered, in place of the epiglottis the larynx contracts and opens, in precisely the way that in the other animals the epiglottis shuts and opens, opening for the entrance and exit of the breath, closing when the nourishment is entering, in order that nothing slip into the windpipe. But if some false note is struck during this sort of movement and someone inhales while taking nourishment, this produces coughing

125. *DA* 2.8.
126. $664^{b}2–3$.

and choking, as was said.[127] In this way the movement both of the epiglottis and the tongue has been so well contrived that when the nourishment is being ground up in the mouth, and is traversing the epiglottis, the tongue seldom falls under the teeth, and it is rare for something to slip into the windpipe.

The animals mentioned[128] do not have the epiglottis because their flesh is dry and their skin hard, so that a part of this sort would not move easily in them, since it is composed of flesh of this sort and skin of this sort, but rather the contraction of the extremities of the windpipe itself occurs as quickly as an epiglottis composed of the proper flesh, which the animals with hair have.

Due to what cause some animals have the epiglottis and others do not, let these be as stated, and also why nature has remedied the badness in the position of the windpipe by devising the so-called epiglottis.

The larynx is situated in front of the esophagus of necessity. For the heart is situated in the front and in the middle—in which part, we say,[129] the starting-point of life and of all movement and perception lies (for perception and movement are toward the so-called front; for it is by this very account that the front and the rear are defined[130])—and the lung is situated where the heart is, that is, around it, and breathing is produced because of this and because of the starting-point being present in the heart.

Breathing, for its part, is produced in the animals through the windpipe; so, since it is necessary for the heart to be situated first among the things in front, it is also necessary for the larynx and the windpipe to be situated in front of the esophagus; for while the former parts extend to the lung and the heart, the esophagus extends into the stomach. And, in general, where nothing else more important impedes it, what is better and more estimable is always, in the case of the above and the below, found more among the things above, and in the case of the front and the rear, more among things in front, and in the case of the right and the left, more among things on the right.[131]

3.4
The Viscera

The neck, esophagus, and windpipe having been spoken about, the next thing to speak about is the viscera. These are special to the blooded animals, and while all are present in some, in others not all are present. None of the bloodless animals has viscera. Democritus seems not to have grasped these things well, if indeed he thought

127. 664b4–6.
128. Those that are hard-scaled or feathered.
129. 647a24–30.
130. *IA* 705b8–13, *Cael.* 284b30–285a10.
131. *IA* 706b11–16.

that, because of the smallness of the bloodless animals, these parts are invisible. For as soon as the blooded animals are composed, and while they are altogether small, both heart and liver become visible. For they are sometimes evident in three-day-old eggs, while they are the size of a point, and very small ones are also evident in aborted fetuses. **$665^{b}1$**

Further, just as with the external parts not all animals have been provided with a use for the same ones, but rather to each a special one has been provided in relation to its mode of life and movements, so it is also natural for the internal parts to be distinct in distinct ones. The viscera are special to the blooded animals, which is also why each of them is composed of bloody matter. This is clear in their newborns; for their viscera are more bloodlike and proportionally largest due to the form of the matter and its quantity being most evident at the moment of the first composition.

A heart is present in all blooded animals; the cause of this was also spoken about previously.[132] For it is clear that it is necessary for the blooded animals to have blood; and since blood is a liquid, it is necessary for a container to be present, for which purpose, in particular, nature appears to have devised the blood vessels. But it is necessary for there to be a single starting-point of these; for wherever possible, one starting-point is better than many. And the heart is the starting-point of the blood vessels; for they manifestly come from the heart and do not go through it, and its nature is blood-vessel-like, as it is of the same kind as them. Its situation is also in a place fitting for a starting-point; for it is around the middle [of the body], and more above than below, and more in front than in back; for nature places the more estimable thing in the more estimable places, where nothing more important prevents it. What has been said is most evident in the case of the human beings, but even in the other animals, the heart tends to be similarly situated in the middle of the necessary body. Of this, a limit is where the residues are secreted; but the limbs vary in various animals, and are not among the parts necessary for life, which is why when they are removed the animals continue living; and it is clear that their addition would not destroy them either.

Those who say that the starting-point of the blood vessels is in the head did not suppose so correctly. For, first, they produce many scattered starting-points; next, these are in a cold place. This is clear, for the head's place is sensitive to cold, while the place around the heart is the contrary. And as was said,[133] while the blood vessels go through the other viscera, no blood vessel extends through the heart; from this too it is clear that the heart is a part—in fact, the starting-point—of the blood vessels. And this is reasonable; for the middle of the heart is a body that is naturally dense and hollow, and further, full of blood, since the blood vessels start from there—hollow to be the receptacle of the blood, and dense to preserve the starting-point of the heat. **$666^{a}1$** For in this part alone of the viscera and the body is there blood without blood vessels,

132. $647^{a}24$–33.
133. $665^{b}15$–17.

while each of the other parts has its blood in blood vessels. This too is reasonable; for the blood is brought from the heart and into the blood vessels, but not to the heart from elsewhere; for this is the starting-point and[134] source of the blood, and its first receptacle. From the dissections these things are clearer, and from the generations;[135] for the heart, which is the first among all the parts that comes to be, is blooded from the outset.

Further, the movements of pleasures and pains and, in general, of all perceptions manifestly have their starting-points there and proceed to it. And this is also in accord with reason; for there must be a single starting-point wherever possible. And the middle is the naturally best disposed of places [for this]; for there is a single middle and accessible from all directions alike, or in much the same way. Further, since none of the bloodless parts is perceptual, nor is the blood, it is clear that the first thing that holds it as in a container is necessarily its starting-point. Not only does it appear to be this way in accord with reason, but also in accord with perception; for in fetuses, the heart is, among the parts, apparently moving from the outset, as if it were an animal, implying that it is a starting-point of movement in the blooded animals. Evidence for what has been said too is the heart's being present in all the blooded animals; for it is necessary for them to have the starting-point of the blood.

The liver is also present in all the blooded animals; but no one would claim it to be a starting-point either of the whole body or of the blood; for it is in no way situated near a position with the form of a starting-point, and it has, like a counterweight, in the most exactly realized animals, the spleen. Further, the liver does not have a receptacle for the blood within itself as the heart does, but like the rest, its blood is in a blood vessel. Further, a blood vessel extends through it, but through the heart none does; for the starting-points of all the blood vessels are from the heart. Since, then, it is necessary for one or the other of these to be a starting-point, and it is not the liver, it is necessary for the heart to be the starting-point also[136] of the blood. For the animal is defined by perception, the primary perceptual part is the primary blooded one, and the heart is a part of this sort; for it is, in fact, the starting-point of the blood and the primary blooded part.

666b1 The extremity of the heart is pointy and solider than the rest, and is situated toward the chest and, in general, in the front of the body, so as for the body not to become cold. For in all animals the chest is more fleshless and the back more fleshy, which is why their heat has a lot of covering in the back.

But while the heart in the other animals is in the middle of the chest's place, in the human beings it inclines a little toward the left, so as to balance the cooling of things on the left; for much more so than the other animals, the human being has left parts that are cold. That in the fishes too the heart is situated in the same way, and why it

134. Reading καὶ.

135. No clear reference to the *Dissections* and *Generation of Animals* seems intended.

136. As well as of the blood vessels.

appears not to be, was stated previously.[137] They have the point of the heart directed toward the head, but this is the front; for their movement is in this direction.

The heart has a great number of sinews, and this is reasonable; for the movements are from it and are effected by contraction and relaxation; it must, then, have equipment of this sort and strength.[138] And the heart, as we said previously,[139] in those that have it, is in nature like a sort of animal. It is boneless in all those that we have actually examined, except for the horses and a certain kind of oxen; in these, due to their great size, there is a bone underneath serving as support, as is also the case for their entire bodies.

The hearts of the larger animals have three cavities, those of the smaller ones two, and all have [at least] one, the cause due to which this is so was stated.[140] For there must also be some place within the heart that is a receptacle of the first blood; and that the blood is first produced in the heart we have said many times.[141] Because the starting blood vessels are two, the one called the "great" and the aorta (for each of these is a starting-point of the blood vessels; and they exhibit differences, which we will speak about later[142]), it is better for their starting-points also to be separated; and this would be so if the blood were different and separated. That is why, in those cases where it is possible, there are two receptacles. And it is possible in the large animals; for their hearts are also large. And it is yet better for there to be three cavities, in order for there to be one common starting-point;[143] and the middle is a starting-point and the odd;[144] so these hearts must always be larger, which is why only the largest hearts have three cavities.

Of these, the ones on the right have the most and the hottest blood (which is also why the parts on the right are hotter), those on the left have the least and the colder blood, while the intermediate ones have blood that is intermediate in quantity and heat, though it is purest; for the starting-point must be most at rest, and it will be like this when the blood is pure but intermediate in quantity and heat.

Hearts also have a sort of division much the same as the sutures [of the cranium].[145] They are not united, as something composed of many things, but, as we said,[146] are more due to articulation. The hearts of animals capable of perceiving are more articulated, while those of the more sluggish are more unarticulated, like those of the pigs.

137. *HA* $506^{b}33$–$507^{a}10$.
138. *MA* $702^{b}20$–25.

142. 3.5.
143. $665^{b}14$–15.
144. The middle point of a line is a starting-point of both equal (or even) segments and is odd because not divisible by 2.
145. $653^{a}37$–$^{b}3$.
146. In analogizing them to sutures.

The differences of the heart with respect to largeness and smallness, and hardness and softness, extend in some way even to the characters of animals. For the animals less capable of perceiving have a heart that is hard and dense, while those [more] capable of perceiving have a softer heart; and those with larger hearts are cowardly, while those with smaller or middle-sized hearts are more confident. For the affection occurring due to fear already exists in these animals, because the heat in their heart is not proportional (since it is small in quantity, it is weakened in large things), and because the blood is colder. Animals with large hearts are the hare, the deer, the mouse, the hyena, the ass, the leopard, the weasel, and pretty much all the others that are manifestly cowardly or due to fear are doers of mischief.

Things are much the same in the blood vessels and in the cavities of the heart; for large blood vessels and cavities are cold. For just as in a smaller and in a larger room an equal-sized fire heats less in the larger one, so it is too with the heat in these parts; for the blood vessel and the cavity are containers. Further, alien movements cool each of the hot things, while in more roomy places the breath[147] is greater, and has more strength; that is why none of those animals with large cavities or large blood vessels has fat in its flesh,[148] but rather all or most of the animals of this sort appear to have inconspicuous blood vessels and small cavities.

Alone among the viscera, and, in general, among the parts in the body, the heart does not withstand any severe affection, and this is reasonable; for when the starting-point has been destroyed, there is nowhere from which aid might come about for the other parts that depend on it. A sign of the heart not admitting of any affection is that in none of the sacrificial animals is any affection of this sort seen in it as in the other viscera. For the kidneys and the liver are often manifestly full of stones, growths, and abscesses, and the same for the lung, and above all the spleen. Many other affections are evident in these viscera, but they are least evident in the lung around the windpipe, and in the liver around the connection to the great blood vessel, and this is reasonable; for it is by this above all that they communicate with the heart. But all those animals that are manifestly dying due to disease, that is, due to affections of this sort, in these, when they have been dissected, morbid affections are evident around the heart.

As regards the heart, then, what sort of thing it is, what it is for the sake of, and the cause due to which it is present in those animals that have it, let this much be said.

147. Inhaled from the cooling environment.

148. It lacks the heat needed to concoct blood into fat (651[b]7–8).

3.5
The Blood Vessels

The next thing would be to speak about the blood vessels, both the great blood vessel and the aorta; for these are the first that receive the blood from the heart, while the remaining ones are offshoots of these. That they are for the sake of the blood, was stated previously;[149] for everything that is liquid has need of a container, the blood-vessel kind is a container, and the blood is in these; but why they are two and why being from one starting-point they extend throughout the entire body, we must now state.

The cause of their ending together in one starting-point and coming from one is that all animals have one soul capable of perceiving actively, so that the part primarily possessing it is also one, one potentially and actively in the case of the blooded animals, but in some of the bloodless ones, actively only.[150] That is also why it is necessary for the starting-point of the heat to be in the same place; and this is the cause both of the liquidity and the heat in the blood. Because, then, the starting-point capable of perceiving[151] and the starting-point of the heat are in one part, [the heat] of the blood also is from one starting-point, and because of the unity of the blood, the unity of the blood vessels too is from one starting-point. There are two blood vessels, though, because the bodies of the blooded animals that move by walking are bipartite; for in all these the front and the back, the right and the left, and the up and the down are distinguished. And by as much as the front is more estimable and more of a leader than the back, by that much is the great blood vessel more so than the aorta; for the former is situated in the front, while the latter is situated in the back, and it is evident that all the blooded animals have the former, though some have it indistinctly and others non-visibly. **668^{a}1**

The cause of the blood vessels being distributed throughout the entire body is that the blood is matter for the entire body (or in the bloodless animals its analog), and this is situated in the blood vessel (or its analog). As for how the animals are nourished, and from what, and in what way they take in the nourishment from the stomach, it is more fitting to investigate and speak about these in the *Generation of Animals*.[152] But since the parts are composed of blood, as we said,[153] it is reasonable that the flow of the blood vessels is naturally through the entire body; for the blood too must go through everything and beside everything, if indeed each of the parts is to be composed of it.

It seems that, just as in gardens irrigation systems are constructed going from one starting-point and source to many and ever many more channels, so as to give a share

149. $665^{b}9$–14.
150. *DA* $411^{b}19$–30, *Met.* $1040^{b}10$–16.
151. $653^{b}5$–8.
152. $740^{a}21$–$^{b}12$, $743^{a}8$–17.
153. $668^{a}3$.

of [water] to all, and in house-building stones are set beside the entire outline of the foundations, in the one case because the garden plants grow from the water, in the other because the foundations are built from the stones, in the same way nature too channels the blood through the entire body, since this is in nature matter for all of it. This becomes clear in those who are especially emaciated; for nothing else is evident besides the blood vessels, just as in grape leaves, fig leaves, and everything else of this sort; for when these leaves too have withered, only their veins[154] remain.

The cause of these things is that the blood (or its analog) is potentially body and flesh (or their analogs); just as, then, during irrigations the largest of the trenches remain, while the smallest are first quickly hidden by the mud, but when it is removed, they become evident again, in the same way too the largest blood vessels remain, while the smallest ones become actively flesh, though potentially they are no less blood vessels. That is also why when the flesh is preserved to any extent whatever, blood flows when it is cut; and further, though without a blood vessel there is no blood, yet no small blood vessel is visible, just as in irrigation systems the trenches are invisible until the mud has been removed.

The blood vessels always proceed from larger to smaller, until the ducts have become smaller than the coarse-grainedness of the blood; though passage through
668b1 them is impossible for the blood, it is possible for the residue of the liquid secretion, which we call "sweat," and this occurs when the body is overheated and the small blood vessels are dilated. And some cases have been observed where sweating resulted in a bloodlike residue because of unhealthiness, when the body becomes flaccid and open-structured, and the blood becomes watery due to lack of concoction, when the heat in the small blood vessels is unable to concoct the blood because of its littleness. For it has been said[155] that every combination of earth and water solidifies when concocted, and nourishment and blood are a mixture of the two of them. But the heat is unable to concoct it not only because of its littleness, but also because of the quantity and excess of the incoming nourishment; for the heat becomes less in relation to this. The excess is of two sorts; for it is both in quantity and in quality; for not all of it can be equally well concocted.

The blood flows most through the roomiest of the ducts; that is why from the nostrils, gums, fundament, and sometimes also from the mouth, painless hemorrhages are produced, not like those from the throat, which are violent.

The great blood vessel and the aorta, being separated above, but crossing each other below, hold the body together. For in proceeding, they divide in accord with the bipartition of the limbs, and the former proceeds from the front to the back, the latter from the back to the front, and they join the body together into one; for just as in things that are plaited together more continuity is found, so too by the blood vessels crossing each other the front of the body is united with the back. The same

154. Literally, "vessels."
155. 649a31–33, *Mete*. 383a13–25.

also happens in the upper places [to blood vessels] coming from the heart. But how exactly the blood vessels stand in relation to each other, one must observe with the help of the *Dissections* and the *History of Animals*.[156]

The blood vessels and the heart may be regarded as spoken about; but the other viscera must be investigated in accord with the same methodical inquiry.

3.6
The Lung

A certain animal kind has a lung because it is terrestrial. For it is necessary for its heat to be cooled, and the blooded animals need to be cooled from outside; for they are hotter. Those that are not blooded are able to cool themselves by their innate breath. It is necessary for cooling from the outside to be by means either of water or of air. That is why none of the fishes has a lung, but in place of this gills, as was said in the studies concerning respiration;[157] for the fishes cool themselves by means of water, while those that breathe do so by means of air, which is precisely why all those that breathe have a lung.

All the terrestrial animals breathe and some of aquatic ones do too—for example, the whale, the dolphin, and all the cetaceans that blow upward. For many animals have a nature that plays a double game, and some that are terrestrial and[158] take in air because of their body's blend spend most of their time in liquid, and some of those that live in liquid participate so much in the terrestrial nature that it is in their breath that the end of living lies.[159]

The lung is the instrument of breathing, deriving the starting-point of its movement from the heart, making plenty of room for the entry of the breath by its sponginess and size; for when it expands the breath flows in, and when it contracts the breath goes out again. It has been said[160]—incorrectly—that the lung is related to the leaping of the heart; for this palpitation happens only (one might say) in the human being, because hope and expectation of the future occur only in him; also in most animals the heart is in a place far distant from the lung and situated in a position higher up than it, so that the lung contributes nothing to the leaping of the heart.

The lung exhibits many differences in the animals. For some have a bloody and large one, others a small and spongy one. The live-bearing ones, because of the heat of their nature, have a large and blooded lung, while the egg-laying ones have a dry and small one, though it is able to open wide during inflation, as in the four-footed egg-laying terrestrial animals—for example, the lizards, the turtles, and every kind of

160. Plato, *Timaeus* 70c.

this sort, and further, in addition to these, those of a winged nature called "birds." For the lung of all these is spongy and like foam; for foam too from being large in volume becomes small when it is compressed, and the lung of these animals is small and membranous. That is why they are all thirst-free and drink little, and are able to live in liquid for a long time; for since they have little heat they can be sufficiently cooled for a long time by the lung's own movement, since it is airy and empty. And this tallies with these animals being smaller in size than the other animals, generally speaking; for heat is growth-productive; and abundance of blood is a sign of heat. Further, heat makes the bodies more upright, which is why the human being is the most upright of all, and the live-bearing animals the most upright of four-footed ones; for none of live-bearing ones, whether footless or going by foot, lives in holes [like the egg-laying ones].

In general, then, the lung is for the sake of breathing, but is bloodless and of such-and-such kind for the sake of certain animals;[161] but what is common to these is nameless, that is, it has no name like "bird" that applies to a certain kind of animal. That is why, just as the being for a bird is composed of something, so too having a lung is present in the substance of these animals.

3.7
The Liver and Spleen

Some of the viscera seem to be of a single nature, such as the heart and the lung, some to be of a double one, such as the kidneys, while some raise a puzzle as to which way they are. For it would appear that the liver and spleen play a double game with respect to these; for in a way each is of a single nature, and in another way, instead of each being one thing, they are two things with much the same nature. But, in fact, all the viscera are of a double nature. The cause of this is that the division of the body, though it is a double nature, contributes to a single starting-point; for there is the up and down, the front and back, the right and left. That is why even the brain tends to be bipartite in all animals, as well as each of the perceptual organs. In accord with the same account, the heart is bipartite too, in its cavities. The lung in the egg-laying animals is divided to such an extent that they seem to have two lungs. The kidneys, for their part, are clearly two in all cases.

As regards the liver and the spleen, though, someone might rightly raise a puzzle. The cause of this is that in those animals that of necessity have a spleen, the spleen would seem to be like a false liver, while in those that do not have one of necessity, but have an altogether small one as a token, the liver is clearly bipartite, one part tending to lie toward the right side, the smaller part toward the left. Nonetheless, even in the egg-laying animals, though it is less evident than in the latter animals,

161. I.e., for their breathing or survival.

in some cases the liver is noticeably divided even there, just as in some live-bearing animals—for example, the hares in some places seem to have two livers, as do some other fishes, especially the selachian-like ones. And it is because the position of the liver is more on the right that the nature of the spleen has come about, so that, while it is in a way necessary, it is not extremely necessary in all animals. **670^{a}1**

The cause, then, of the nature of the viscera being double, as we said,[162] is that the right and the left are two; for each seeks its like. And just as these [viscera] tend to be much the same and to have the nature of twins, and[163] just as those [sides], though they are twins, are joined together into one, it is also the same way for each of the viscera.

Viscera that are below the diaphragm are all in common for the sake of the blood vessels, in order that, though unsupported, they remain attached to the body, with these as bond of union. For they are just like anchor-lines, which have been thrown in the body through the extended parts, going from the great blood vessel to the liver and the spleen; for the nature of these viscera is to be like nails that fasten the great blood vessel to the body, while the liver and the spleen fasten it to the sides of the body (for the blood vessels extend from the great blood vessel to these parts alone), and the kidneys to the back. To each of the kidneys a blood vessel extends not only from the great blood vessel, but also from the aorta. These are the things, then, that result due to the viscera in the composition of the animals. The liver and the spleen also aid in the concoction of the nourishment (for since they are blooded they have a hot nature), while the kidneys aid in [collecting] the residue secreted into the bladder.

The heart and the liver are necessary to all animals, the heart because there must be a starting-point of the heat (for there must be something like a hearth, in which the vital spark of the animal's nature is situated, and this must be well protected, since it is, as it were, the acropolis of the body), the liver for the sake of concoction. All the blooded animals must have these two, that is why these two alone are viscera that all the blooded animals possess; but those that breathe have a third, the lung.

The spleen is coincidentally present of necessity, in those that have one, as are the residues, both the one in the stomach and the one around the bladder. That is why the spleen is deficient in size in some cases, as in all the feathered animals that have a hot stomach—for example, the pigeon, the hawk, and the kite; it is the same way in the egg-laying four-footed animals (for they have an altogether small one) and in many of the soft-scaled ones. These are precisely the ones that also lack a bladder, because the residue is directed through their open-structured flesh into feathers and soft scales. For the spleen draws off the residual wet secretions from the stomach, and is able to help concoct them, since it is bloodlike. But if the residue is too abundant or the spleen has a small quantity of heat, the [animals] become sickly from being full of nourishment; and because of the reflux of the liquid there, in many animals whose **670^{b}1**

162. 669^{b}18–21.
163. Reading καὶ.

spleen is sick the stomachs become hard, as with those animals that are inclined to urinate a lot, because their liquid has been drawn off.

In those animals that produce a small quantity of residue, like the birds and the fishes, some do not have a large spleen, while others have a token one. In the four-footed egg-laying animals the spleen is small, firm, and kidney-like, because their lung is spongy and they drink little, and because the surplus residue is directed to their body and their hard scales, just as it is to the feathers in the birds. In those that have a bladder and a blooded lung the spleen is wet, both due to the cause mentioned[164] and because the nature of things on the left side is generally wetter and colder. For each of the contraries has been placed by division in the column of things of the same kind—for example, right contrary to left and hot contrary to cold; and the columns are related to each other in the way mentioned.[165]

The kidneys are present in those that have them not of necessity, but for the sake of the well and the good;[166] for, in accord with their special nature, they are for the sake of the residue that collects in the bladder in those animals in which a greater quantity of this sort of sediment is produced, in order that the bladder do its own work better.

But since it is for the sake of the same need that animals are found to have the kidneys and the bladder, the bladder must now be spoken about by stepping over the next part in order; for nothing has yet been determined about the diaphragm, though this is one of the parts near the viscera.

3.8
The Bladder

Not all animals have a bladder, rather nature seems to wish to provide it only to those **671^a1** with a blooded lung, and reasonably only to them. For because of the excess of the nature[167] that they have in this part, these are the most thirsty of animals, and need not only more dry nourishment, but also more wet, so that of necessity more residue is produced, and not only as much as is concocted by the stomach and secreted with its own residue. It is necessary, therefore, for there to be something receptive of this residue as well. That is why those animals with a lung of this sort all have a bladder. Those that do not have a lung of this sort, but either drink very little because they have a spongy lung, or generally take in liquid for the sake not of drink but of nourishment (for example, the insects and the fishes), and further, those that are feathered, soft-scaled, or hard-scaled, because of the small quantity of liquid taken in and the

164. 670^b4.
165. I.e., the right and the hot are in the same column as are the left and the cold.
166. 640^a35–^{b}1, 645^a25–26.
167. I.e., the heat of the blood.

surplus residue being directed to these parts—none of these has a bladder, except for, among the hard-scaled animals, the turtles.

And there alone nature has been docked [in its operations]. The cause of this is that the sea turtles have a lung that is fleshy and blooded, like that of the cow, while the land turtles have one that is disproportionally large. Further, because the encompassing body is hard-shell-like and dense, the liquid does not dissipate through their open-structured flesh, like in the birds, the snakes, and other hard-scaled animals, so that so much sediment is produced that their nature must have some part that is receptive and container-like. This, then, is the cause due to which these are the only animals of this sort that have a bladder, the sea turtle a large one, the land turtles an altogether small one.

3.9
The Kidneys

It is the same way with the kidneys too. For none of the feathered, soft-scaled, or hard-scaled animals has kidneys either, except for the sea turtles and the land turtles; although—as if the flesh assigned to the kidneys had no place, but was dispersed to many places—there are flat kidney-like parts in some of the birds.

The freshwater turtle has neither a bladder nor kidneys; for because of the softness of its shell the liquid is easily evaporated. This, then, is the cause due to which the freshwater turtle has neither of these parts; but the other animals with a blooded lung, as was said,[168] are all found to have kidneys. For nature uses these at the same time for the sake of the blood vessels and for the secretion of the liquid residue; for a duct goes to them from the great blood vessel. **$671^{b}1$**

The kidneys all have a cavity, either large or small, except for those of the seal; these, being like those of the cows, are the most solid of all. The kidneys of the human beings are also like those of the cows; for they are, as it were, composed of many small kidneys and do not have a smooth surface like those of the sheep and the other four-footed animals. That is also why an infirmity of the kidneys in human beings is difficult to get rid of, once they get sick; for since it is as if they had many diseased kidneys, the treatment is more difficult than if one were diseased.

The duct that extends from the blood vessel does not terminate in the cavity of the kidneys, but is used up in the body of the kidneys; that is why blood is not found in their cavities, nor does it solidify there when the animals die. But from the cavities of the kidneys two sturdy bloodless ducts[169] go to the bladder, one from each of them, and other strong and continuous ones go to the kidneys from the aorta. These things are arranged in this way in order that from the blood vessel the residue of the liquid

168. $670^{b}32$–$671^{a}8$.
169. The ureters.

can travel to the kidneys, while from the kidneys the sediment produced from the filtering of the liquids can flow through the body of the kidneys into their center, where most of them have their cavity. That is also why they are the most foul smelling of the viscera. And from the center through these ducts something that is already more like a residue is secreted into the bladder. The bladder is suspended from the kidneys; for strong ducts, as was said,[170] extend to it. These, then, are the causes due to which the kidneys exist, and have the capacities mentioned.

In all the animals with kidneys, the right one is higher up than the left; for because their movement starts from the parts on the right, and because of this the nature of the parts on the right is stronger, all these parts must, because of the movement, tend in advance more upward, since they even raise the right eyebrow more and have it more arched than the left. And because the right kidney is drawn up higher, the liver is in contact with it in all these animals; for the liver is on the right.

672[a]1 The kidneys have the most fat of all the viscera, in part, of necessity, because the residue is filtered through the kidneys; in fact, the remaining blood, since it is pure, is easily concocted, and the end of well-concocted blood is fat and suet. For just as in dry things that have been burned, like ashes, some fire is left behind in them, so it is too in wet things that have been concocted; for some of the heat that did the work is left behind in them. That is why what is oily is light and rises to the surface in liquids. However, the fat is not produced in the kidneys themselves, because this viscera is dense, but surrounds them on the outside—fat in those animals that are fatty, suet in those that are suety; the difference between these was stated previously elsewhere.[171]

Of necessity, then, the kidneys come to be fatty due to this cause: from what happens of necessity in animals with kidneys. But they also come to be fatty for the sake of the preservation of the kidneys and their natural heat. For since they are outermost, they need more heat; for while the back is fleshy, so that it is a protection for the viscera around the heart, the loin is fleshless (for the bending-points of all animals are fleshless); in place of flesh, then, the fat becomes a shield for the kidneys. Further, they disaggregate and concoct the liquid better when they are fat; for what is oily is hot, and heat concocts.

It is due to these causes, then, that the kidneys are fatty, though in all animals the right one is less fatty. The cause of this is that the nature of the parts on the right is dry and more capable of movement; and movement is contrary [to being fatty]; for it melts the fat more.

For the other animals it is advantageous to have fat kidneys, and often they have their whole kidneys full of fat; although when a sheep is affected in this way, it dies. But even if the kidneys are very fat, nonetheless, there is some deficiency, if not in both, at least in the right. The cause of this happening only or most of all in the case of the sheep is that in fatty animals the fat is liquid, so that their outbursts of wind

170. 671[b]16, *HA* 497[a]11–13.
171. 2.5, *HA* 3.17–18.

do not cause trouble to the same extent by becoming enclosed. For this is a cause of gangrene; that is also why, among the human beings, those who suffer from pains in their kidneys, and even though it is advantageous for the kidneys to be fat, nonetheless if they become very fat, mortal pains result.

Among the other animals, the suet in the suety ones is less dense than in the sheep. And in its quantity the sheep greatly exceed other animals; for the sheep are **672^b1** the fastest of all the animals to become fat around the kidneys. When the liquid and the outbursts of wind become enclosed, then, the sheep are quickly done away with due to gangrene; for through the aorta and the blood vessel the condition makes its way directly to the heart; for there are continuous ducts from these blood vessels to the kidneys.

3.10
The Diaphragm

The heart and lung have been spoken about, then, also the liver, spleen, and kidneys.

These are separated from each other by the diaphragm. This diaphragm some people call the "midriffs"; it is what divides the heart and lung from the others. And in the blooded animals this diaphragm is called the "midriffs," as was just said. All the blooded animals have it, just as they do a heart and a liver. The cause of this is that it is for the sake of the division of the place around the stomach from the one around the heart, so that the starting-point of the perceptual soul will be unaffected and not be quickly overwhelmed by the exhalation coming from the nourishment and the large quantity of the heat brought in from outside. It is for this that nature established a division, making the midriffs like a partition wall or fence to divide the more estimable and the less estimable, in those animals in which it is possible to divide the upper and lower; for the upper is the for-the-sake-of-which and better, while the lower, the receptacle for the nourishment, is for the sake of it and necessary.

The diaphragm is fleshier and stronger toward the ribs, more membranous in the middle; for in this way it is more useful for strength and elasticity. As to why there are sorts of appendages against the heat from below, a sign is provided by what happens; for when, because of their proximity, the midriffs draw in the hot residue-like liquid, it right away noticeably disturbs thought and perception; that is why, indeed, they are called "midriffs (*phrenes*)," on the supposition that they participate in some way in thinking (*phronein*). In fact, they do not participate in it at all, but by being near to those things that do, they produce a noticeable change in thought. That is also why they are thin in the middle, not only of necessity (because, since they are fleshy, the parts of them that are toward the ribs are necessarily fleshier), but also in order that they participate as little as possible in the liquid secretion; for, since they are fleshy, they would retain and draw in much more secretion. **673^a1**

Another sign that the midriffs noticeably produce perception when quickly heated is also what happens in regard to laughter. For those who are tickled laugh quickly because of the movement that quickly arrives at this place, and, though heating but slightly, it nonetheless produces a noticeable effect and moves thought contrary to deliberate choice. The cause of the human being alone being ticklish is at once the thinness of his skin and the fact that the human being is the only one among the animals that laughs. And tickling is laughter caused by a movement of this sort in the part of the body around the armpit.

Laughter also results, they say, in connection with blows struck in battle to the place around the midriffs, due to the heat arising from the blow. Indeed, this comes from reports more trustworthy than the one about the human head that continues speaking after it has been cut off. For some people say, even invoking Homer, that it is because of this that he wrote, "and as *it* spoke his head was mingled with the dust" (not "as *he* spoke"[172]). In Caria this sort of thing was so thoroughly believed that one of the inhabitants was put on trial concerning it. For when the priest of Zeus the Warrior was killed, and it was unknown by whom, some people claimed to have heard the cut-off head saying many times, "Cercidas killed, man to man." That is why in fact, having searched for and found someone in the place whose name was "Cercidas," they put him on trial. But it is impossible to speak when the windpipe has been severed, and without movement coming from the lungs. And among the barbarians, where they cut off heads with alacrity, nothing of this sort has ever occurred. Further, due to what cause does this not occur in the other animals?

The report about laughing when the midriffs are struck makes perfect sense; for none of the other animals laughs. And that the body advances some distance after it has been separated from the head is not at all unreasonable, since the bloodless animals actually go on living for a long time. The causes of these things have been made clear elsewhere.[173]

What each of the viscera is for the sake of, then, has been stated. But they occur of necessity at the internal limits of the blood vessels; for it is necessary for a liquid secretion that is bloodlike to go out there, from which, once it has been condensed and solidified, the body of viscera is composed. That is why the viscera are bloody, and why the nature of their body is the same, and unlike that of the other parts.

3.11
The Membrane of the Viscera

All the viscera are in a membrane; for, for them to be unaffected, there must be a protection, and this must be light, and the membrane is in nature something of this

172. *Iliad* 10.457, *Odyssey* 22.329.
173. E.g., *DA* 411b19–27, 413b19–24, *HA* 531b30–532a5

sort; for it is dense so as to protect against the influx of liquid, fleshless so as not to draw in or retain liquid secretion, and thin in order to be light and not produce weight. The largest and strongest of the membranes are those around the heart and the brain, and this is reasonable; for these parts are in need of the most protection. For the protection is a protection around the controlling parts, and these parts most of all control life.

3.12
Differences in the Viscera (1)

Some animals have every one of the viscera, some do not have all; what sorts do not, and due to what cause, was stated previously.[174] But even among those that have them these parts differ; for the hearts are not the same in all animals that have a heart, and none (one might almost say) of the others is either.

For the liver in some animals is divided into many parts, while in others it is more of a single nature, first and foremost in the blooded live-bearing animals themselves; further, both in comparison to the former animals and in comparison to each other, the livers of the fishes and of the four-footed egg-laying animals differ more. The liver of the birds is most like the liver of the live-bearing animals; for its color is pure and bloodlike, just like theirs. The cause of this is that their bodies breathe freely, and do not have much inferior residue.[175] That is also why some of the live-bearing animals have no bile; for the liver contributes in large part to the good blend and health of the body; for the end of these viscera lies above all in the blood; and the liver is the most blooded of the viscera after the heart. The livers of most of the four-footed egg-laying animals and of the fishes are yellowish, and those of some are in fact altogether inferior, just as their bodies too have an inferior blend—for example, those of the toad, the turtle, and other animals of this sort.

The horned cloven-hoofed animals, like the goat, the sheep, and each of the others, has a round spleen, unless, because of the animal's magnitude, it grows more in length, as happens with the spleen of the cow. The multi-split-footed animals all have a long spleen—for example, the pig, the human being, and the dog; the solid-hoofed **674ᵃ1** ones have a spleen that is intermediate between, and a mixture of, these two; for it is in one part broad and in another part narrow—for example, the horse, the mule, and the ass.

174. 670ᵃ23–ᵇ31.

175. The presence of which in the blood would render it impure and darker.

3.13
Differences in the Viscera (2)

The viscera differ from the flesh not only in the bulk of their body, but also in that they are situated on the inside, not on the outside. The cause of this is that they have a nature that participates in [the nature of] the blood vessels, that is, some exist for the sake of the blood vessels, while others do not exist without the blood vessels.

3.14
The Stomach

Beneath the diaphragm is situated the stomach in animals; in those with an esophagus it is where this part ends; in those without one it is immediately next to the mouth; and following the stomach is the so-called intestine. The cause due to which each of the animals has these parts is evident to everyone. For it is necessary for the incoming nourishment to be received, for the nourishment that has been deprived of liquid to be expelled, and for the unconcocted nourishment and the residue not to be in the same place; and there must be also some place in which the nourishment is changed. For one part will hold the incoming nourishment, the other part the useless residue; and just as the time of each of these is distinct, it is necessary for them to be distinguished by their places too. But while the definition of these parts is more appropriate to the *Generation of Animals* and *On Nourishment*,[176] the differences of the stomach and of the contributing parts must be investigated now. For the animals have stomachs that resemble each other neither in their sizes nor in their forms.

All the blooded live-bearing animals with two rows of teeth have one stomach—for example, the human being, the dog, the lion, and all the other many-toed animals; all those that are solid-hoofed—for example, the horse, the mule, and the ass; and all those that, though solid-hoofed, have two rows of teeth—for example, the pig—except when, due to the magnitude of its body and the capacity of it nourishment, which is not easy to concoct, but instead is thorny and wood-like, the animal has more than one stomach—for example, the camel does, just like the horned animals. For the horned animals do not have two rows of teeth. And it is because of this that the camel, though without horns, does not have two rows of teeth either: because of the greater necessity of its having a stomach of this sort than having front teeth. So, since the camel has a stomach like the one of the animals without two rows of teeth,
674b1 it is also like them as regards its teeth, since these have no work. But at the same time, since its nourishment is thorny, and it is necessary for the tongue to be fleshy, nature uses the earth from the teeth for hardening the roof of the mouth.

176. 650b8–11.

The camel also chews the cud, just as the horned animals do, because it has stomachs like theirs. Each of these animals has several stomachs—for example, the sheep, the cow, the goat, the deer, and the other animals of this sort—in order that, since the service of the mouth is deficient as regards working on the nourishment because of the want of teeth, the stomachs receive the nourishment one after the other: the first unworked up, the next more worked up, the next altogether worked up, the last ground up. That is why animals of this sort have several places and parts. These are called "stomach," "net," "vase," and "reed." The way these parts are related to each other in their position and forms must be observed with the help of the *History of Animals* and the *Dissections*.

Due to the same cause, the bird kind also exhibits difference as regards the part that is receptive of the nourishment. For since they also do not fully do the work of the mouth (for they are toothless and have nothing with which to cut up or grind up the nourishment), because of this some birds have a so-called crop in front of the stomach in place of the working of the mouth; some have their esophagus broad, either as a bulky part of it in front of the stomach, in which to store the unworked-up nourishment, or else as a projecting part of the stomach itself; and some have the stomach itself strong and fleshy so as to be able to store the nourishment for a long time and to concoct it although it is not ground up; for by the capacity and heat of the stomach nature makes up for the deficiency of the mouth. But there are some birds that have none of these things, but rather a long crop, all the ones that are long-legged and live in marshes, because of the wetness of their nourishment. The cause of this is that the nourishment for all these birds is easily ground up, so that it follows because of these things, because of the lack of concoction and the [sort of] nourishment, that the stomachs of these birds are wet.

The fish kind has teeth, and pretty much all of them, one might say, are saw-toothed; for one small kind is not like this, namely, the so-called parrot wrasse, which seems indeed to be the only one to chew the cud, and this is reasonable because of this; for the horned animals without two rows of teeth also chew the cud. All the fishes have sharp teeth, so that they are able to cut up nourishment, though they cut badly; for they cannot spend the necessary time. That is why they neither have broad teeth nor are able to grind up nourishment: it would be pointless to have them. **675^{a}1**

Further, as for a gullet, some fishes do not have one at all, while others have a short one. But to aid with concoction some fishes have stomachs that are bird-like and fleshy—for example, the mullet; but many have appendages densely packed together next to the stomach, in order that by storing it in these, as if in reservoirs, they can decompose and concoct the nourishment. The fishes, though, have these appendages in a contrary way to the birds; for the fishes have them up near the stomach, while in the birds that have appendages they are down near the end of the intestine. Some live-bearing animals also have some intestinal appendages down below due to the same cause.

The entire fish kind—because the parts having to do with working on the nourishment are so deficient that they excrete it unconcocted—is gluttonous for nourishment, and so are all the other animals that have a straight intestine. For since the excretion occurs quickly, and because of this their enjoyment is short, it is necessary for the appetite to occur again quickly too.

That the animals with two rows of teeth have a small stomach was stated previously,[177] and pretty much all of them fall into two different sorts; for some have a stomach like that of the dog, others like that of the pig. That of the pig is larger and has some folds of moderate size, in view of the longer time it takes for concoction to occur, while that of the dog is small in size, not greatly exceeding that of the intestine, and smooth inside.

After the stomach lies the nature of the intestines in all the animals. Like the stomach, this part too exhibits many differences. For in some animals it is simple and alike when uncoiled, while in the others it is not alike; for in some the part near the stomach is wider, the one near the end narrower (that is why the dogs release this sort of residue with difficulty), but in most it is narrower above, wider near the end. The intestines of the horned animals are larger and have many convolutions, and the bulk of the stomach and of the intestines in these animals is greater, because of their large size; for (one might almost say) all the horned animals are large due to their nourishment's being worked up. In all those animals with intestines that are not straight this part becomes wider as it proceeds, and they have a so-called colon, and the blind and bulky part of the intestine; then, from this point, it gets narrower again and coiling. The part after this extends straight to the outlet for the residue; in some this part, which is called the "anus," is fatty, in others devoid of fat.

All these parts have been devised by nature for the appropriate workings on the nourishment and on the residue produced. For as the residue proceeds downward it comes into a roomier place, where it remains in order to undergo change in those animals that are more receptive of and requiring more nourishment, whether because of their size or the heat of the place. Then, in turn, just as a narrower intestine receives it from the upper cavity,[178] so from the colon and the roomier place in the lower cavity, it again goes into a narrower place, and then into the spiral coil, when the residue has been altogether deprived of liquid, in order that nature can store it and the emission of the residue not occur all at once.

All those animals that must be more temperate in regard to the production of nourishment do not have roomy places in the lower cavity that are large, but instead have many spirals and intestines that are not straight. For roominess produces an appetite for a large quantity of nourishment, while straightness produces quickness of appetite's [return]; that is why among all those animals that have simple receptacles or roomy ones, the latter are gluttonous in terms of quantity, the former in

177. 674[a]23–25.
178. The stomach.

terms of quickness. But since in the upper receptacle, during the first entrance of the nourishment, it is necessarily fresh, and as it proceeds downward, excrement-like and deprived of liquid, it is also necessary for there to be some intermediate place in which it undergoes change and is neither still fresh nor already excrement.

It is because of this that all animals of this sort have the so-called fasting-place, in the thin intestine after the stomach; for this is intermediate between the upper one, in which the unconcocted nourishment is, and the lower one, in which the already useless residue is. This place is found in all animals, but is clear to perception in those that are larger and when they have fasted, not when they have eaten. For it is when **676ª1** they are fasting that a middle place between the two places is found, but when they have eaten the opportune time for undergoing the change is short. In the females the fasting-place is found anywhere in the upper part of the intestine, while the males have it before the blind place[179] of the lower cavity.

3.15
Rennet

All the multi-stomached animals have the so-called rennet, and among the single-stomached ones, the hare. The multi-stomached ones have the rennet neither in the large stomach, nor in the net, nor in the last one, the reed, but rather in the one intermediate between the last one and the two first ones, the one called the "vase." All these have rennet because of the coarse-grainedness of their milk; but the single-stomached ones do not have it, for the milk of the single-stomached ones is fine-grained. That is why the milk of horned animals solidifies, while that of the hornless ones does not solidify. Rennet is produced in the hare, though, because it feeds on herbs with a fig-like juice; for juice of this sort composes the milk in the stomach of the sucklings. Why, among the multi-stomached animals, rennet is produced in the vase was stated in the *Problems*.[180]

BOOK 4

4.1
The Viscera of the Four-Footed Egg-Laying Animals and the Snakes

As regards the viscera, the stomach, and each of the other parts mentioned, they are the same way in the four-footed egg-laying animals and the footless ones such as the snakes. In fact, the nature of the snakes is of the same kind as that of these;

179. Secluding καὶ.
180. Not in our text of that title.

for it is like that of a long, if also footless, lizard. And all these parts are much the same in these animals and in the fishes too, except that they have a lung, because they are terrestrial, while the fishes do not have one, but have gills in place of a lung. Neither the fishes nor any of these animals have a bladder, except for the turtle; for the liquid is diverted into their scales (since they drink little because of the bloodlessness of their lungs), just as in the birds it is diverted into the feathers. And in all these animals the residue is whitish, as it also is in the birds. That is why, in those animals that have a bladder, when the residue flows out, and earthen salt settles in its receptacles; for the sweet and drinkable part is used up, because of its lightness, for the flesh.

The vipers exhibit the same difference in relation to the other snakes as the selachians do in relation to the other fishes; for both the selachians and the vipers are externally live-bearing, after being internally egg-laying first.

All animals of this sort are single-stomached, just like the others that have two rows of teeth; they also have altogether small viscera, like others that do not have a bladder. But in the snakes, because of the shape of their body, which is long and narrow, the configuration of the viscera is also long because of this, and unlike that of the other animals, because, just as in a mold, their configurations are shaped by the place.

All the blooded animals have an omentum, a mesentery, and the parts having to do with the nature of the viscera, and further, a diaphragm, a heart, and—except for the fishes—a lung and a windpipe. And the position of the windpipe and the esophagus is the same in all that have them due to the causes stated previously.[181]

4.2
The Gallbladder

Most of the blooded animals also have a gallbladder, some attached to the liver, others attached to the intestines, since its nature, no less than of these, is that of the lower stomach. This is most clear in the case of the fishes; for they all have a gallbladder, most of them near the intestines, though some have it woven along the whole intestine—for example, the bonito; most of the snakes have it in the same way. That is why those who say[182] that the nature of the gallbladder is for the sake of a certain sort of perception are not correct. (For they say that it exists because of the following, in order that when [the bile] is stinging the part of the soul around the liver, it makes [people] frown, but when it is released, it makes [people] cheerful.) For some animals have no gallbladder at all—for example, the horse, the mule, the ass, the deer, and the

181. 665a16–22.
182. Plato, *Timaeus* 71d.

roe deer. The camel does not have a separate one either, but rather has gallbladder-like blood vessels. The seal has no gallbladder at all either, nor, among the marine animals, does the dolphin.

Within the same kind, some appear to have a gallbladder, others not to have one—for example, in the mice kind. The human being is also among these kinds; for some appear to have a gallbladder attached to the liver, while others do not. That is why in fact a dispute occurs about the entire kind; for those who happen upon one of the two suppose that all of them—absolutely all of them—are that way. This sort of thing also happens with regard to the sheep and the goats; for while most of them have a gallbladder, in some places—for example, in Naxos—it is so large that the excess seems to be monstrous, but in other places they do not have one—for example, in Chalcis in Euboea, in a certain place in their country. Further, as was said,[183] the gallbladder of fish is much detached from the liver.

The followers of Anaxagoras seem to have supposed incorrectly that bile is a cause of the acute diseases (for when it is excessive, it flows, they think, to the lung, the blood vessels, and the ribs). For pretty much all of those in whom these diseased conditions occur have no gallbladder, and this would become evident in dissections; further, the quantity of bile present in these illnesses is incommensurable with that sprinkled about.[184] Instead, just as the bile, when it occurs in the rest of the body seems to be a residue or a colliquescence, so also the bile near the liver seems to be a residue and not to be for the sake of something, just like the sediment in the stomach and that in the intestines. Sometimes, to be sure, nature even uses residues for some beneficial thing; but it is not necessary, because of this, to seek what something is for the sake of in every case; on the contrary, when certain things are of the sort they are, many other things happen of necessity.

Those animals in which the composition of the liver is healthy, and the nature of the blood secreted into it sweet, either do not have any gallbladder at all near the liver, or the bile is in small blood vessels, or else some have it, while others do not. That is also why the livers of those animals without a gallbladder are, generally speaking, bright-colored and sweeter; of those with a gallbladder, the part of the liver below the gallbladder is sweetest. But from those livers composed of less pure blood, the residue that is produced is the bile. For the residue tends to be contrary to the nourishment, and bitter is contrary to sweet, and the sweet blood is the healthy blood. It is evident, then, that bile is not for the sake of anything, but is instead a by-product.

That is why in fact, among the ancients, the ones who say that a cause of living for a long time is not having bile are most sophisticated, after having looked at the solid-hoofed animals and the deer; for these animals are without bile and also live a long time. Further, there are animals, not observed by them, that do not have bile,

183. $676^{b}16$–20.

184. As evidenced (perhaps) by the quantity of yellow bile stains found around the gallbladder.

like the dolphin and the camel, and these also turn out to be long-lived. For since the nature of the liver is vital and necessary for all the blooded animals, it is reasonable that its being of a certain quality is a cause of living for a shorter or a longer time. **677ᵇ1** And that the residue of this viscera is of this sort, and not that of any of the others, is in accord with reason. For no humor of this sort can be near the heart (for the heart does not accept any forceful affection), and none of the other viscera is necessary to these animals, but the liver alone; that is also why this humor occurs around it alone. And it would be absurd not to think that phlegm or sediment from the stomach is a residue wherever one sees it; likewise, it is clear that the same applies to the bile and that it does not differ in its places.

4.3
The Omentum

As regards the gallbladder, then, the cause due to which some animals have it and others do not have it has been stated. It remains to speak about the mesentery and the omentum. For these are in the place and among the parts that are under discussion.

The omentum is a membrane that is suety in those animals that have suet, and fatty in those animals that have fat. Of what sort each of these is was stated previously.[185] The omentum has its starting-point, in the single-stomached and the multi-stomached animals alike, from the middle of the stomach along the line traced on it like a suture. It extends over the remainder of the stomach and the mass of the intestines in the blooded animals, in the terrestrial, and in the aquatic ones alike.

The generation of this part occurs of necessity as follows: for when a mixture of dry and wet is heated, the surface always becomes skin-like and membranous, and this place is full of nourishment of this sort. Further, because of the thickness of the membrane, it is necessary for the part of the bloodlike nourishment that is filtered through it to be fatty (for this is the most fine-grained), and, because of being concocted by the heat in this place, instead of being a flesh-like and bloodlike composition, it is necessary for it to become suet or fat.

The generation of the omentum, then, occurs in accord with this account, and nature uses it for the good concoction of the nourishment, in order that the animals concoct their nourishment more easily and quickly; for what is hot is able to concoct, what is fatty is hot, and the omentum is fatty. And because of this it has its starting-point from the middle of the stomach, because the part that is situated near it, the liver, aids in concoction.

The omentum, then, has been spoken about.

185. 2.5, *HA* 3.17–18.

4.4
The Mesentery

The so-called mesentery is a membrane but extends continuously from the long stretch of the intestines to the great blood vessel and the aorta, and is itself full of many densely packed together blood vessels that extend from the intestines to the great blood vessel and the aorta. **678ª1**

We will find that its generation is of necessity, like that of the other parts. Due to what cause it is present in the blooded animals is evident on investigation. For since it is necessary for the animals to take in nourishment from outside, and again for the final nourishment to come from this, and for an immediate distribution of it to be made to the parts (this final nourishment is nameless in the bloodless animals, but in the blooded ones it is called "blood"), there must be something through which the nourishment will be carried, like through roots, from the stomach into the blood vessels. But while the plants have their roots in the earth (for it is from there that they get their nourishment), for the animals the stomach and the capacity of the intestines is earth, from which they must get their nourishment. That is why it is the nature of the mesentery to have blood vessels, like roots, going through it. What the mesentery is for the sake of, then, has been stated; but in what way it gets the nourishment, and how what is distributed to the blood vessels, by going through the blood vessels from the incoming nourishment, enters these parts in question, will be discussed in the *Generation of Animals* and *On Nourishment*.[186]

How the blooded animals have the parts that have been distinguished up to this point, then, and due to what causes, has been stated. The parts that contribute to generation, by which the female and male seem to differ, are the next ones remaining to be spoken about; but since generation must be spoken about, it is appropriate to speak about these parts too in the theoretical investigation concerning those subjects.

4.5
The Bloodless Animals

Those animals called "soft-bodied" and "soft-shelled" exhibit many differences in relation to those animals;[187] for first of all, they do not have the nature of the viscera at all. Similarly, none of the other bloodless animals has it either. And there are two remaining kinds of bloodless animals, the hard-shelled ones and the insect kind. For none of these animals has what the nature of the viscera is composed of, blood, because this sort of affection[188] is something belonging to their substance; for that

186. $650^{b}8$–11.
187. The blooded ones.
188. The absence of blood.

some animals are blooded and others bloodless will be present in the account defining their substance. Further, none of the things for the sake of which the blooded animals have the viscera will be present in animals of this sort; for they have neither blood vessels nor a bladder nor do they breathe; instead, it is alone necessary for these to have the analog of the heart. For, in all the animals, the perceptual part of the soul and the cause of life belong to a certain starting-point of the parts and of the body. And they all have the parts for nourishment of necessity as well; but their ways of getting their nourishment differ because of the places in which they get it.

The soft-bodied animals have two teeth around the part called the "mouth," and in the mouth, in place of a tongue, something fleshy, with which they discern the pleasantness of what they eat. In the same way, the soft-shelled animals also have these primary teeth and the fleshy analog of the tongue. Further, all the hard-shelled animals have a part of this sort, due to the same cause as in the blooded animals, for the perception of the nourishment. Similarly, the insects in some cases—for example, the bee kind and the fly kind—have a proboscis protruding from their mouth, as was said previously;[189] but those that do not have a sting in front, have a part of this sort inside the mouth—for example, the ant kind and any other animals of this sort there may be. Some insects have teeth, but of quite another sort, just as the fly kind and bee kind do, while others—all those that use liquid nourishment—do not have them. For many insects have teeth not for nourishment but for strength. Some of the hard-shelled animals, as was also said in the accounts at the start,[190] have the so-called strong tongue, while the spiral-shelled ones have two teeth, like the soft-shelled animals.

After the mouth, in the soft-bodied animals, there is a long gullet, following it a crop, like in the birds, then, continuous with it, a stomach, and following it a simple intestine until the outlet. In the cuttlefishes and the octopuses, the parts around the stomach are alike in configuration and to the touch; but while in the ones called "calamaries" there are similarly two stomach-like receptacles, one of the two is less crop-like, and these parts differ in shape from those in the former animals because the entire body is also composed of softer flesh. These animals have these parts in this way due to the same cause as the birds also do; for none of them is able to grind up the nourishment, which is precisely why the crop is in front of the stomach.

For protection and preservation these animals have the so-called ink, which forms in a membranous sac, with its outlet and limit exactly where the residue of the stomach is released through the so-called pipe; and this is in their underneath parts. All the soft-bodied animals have this special part, but most of all and in the greatest quantity, the cuttlefish; for when it is frightened and alarmed, as a protection in front of its body, it makes the water black and inky. The calamaries and the octopuses have the

189. 661ª15–20.
190. Perhaps 661ª20–24, also *HA* 528ᵇ30–33.

ink above, nearer to the *mutis*,[191] while the cuttlefish has it below near the stomach; for it has more because it uses it more. And this happens to it because, though it lives its life inshore, it has no other means of protection, in the way that the octopus has its useable tentacles[192] and change of color, which happens to it, just as the release of ink also does, because of cowardice. (Among these animals, the calamary is the only deep-sea dweller.) The cuttlefish, then, has more ink because of this, and has it lower down because there is more of it; for it is easily released, even from a distance, because of its greater quantity. The ink occurs just as in the birds a white earthen sediment on their residues does: so in these animals too the ink occurs because they do not have a bladder; for the most earthen part is secreted into the ink; and the largest quantity in the cuttlefish because it is the most earthen. A sign of this is that its cuttlebone is of this sort; for the octopus does not have this, while the calamaries have one that is cartilaginous and thin. Due to what cause some have it and others do not, and what sort each of them has, was stated.[193]

These animals are bloodless, and because of this they are chilled and fearful, and just as in some animals, when they are alarmed, the stomach gets disturbed, while in others residue flows from the bladder, so in these animals the release occurs of necessity because of cowardice, just as it does from the bladder in animals that urinate, but nature at the same time uses this sort of residue for protection and preservation.

The soft-shelled animals, both those of the crayfish form and the crabs, have the two primary teeth, and between them the tongue-like flesh, as was also said previously;[194] immediately following the mouth they have a gullet that is small in comparison to the [great] size of their bodies (the comparative greatness being relative to the comparative smallness); following this they have a stomach, in which the crayfishes and some of the crabs have other teeth, because the upper ones do not cut sufficiently; and from the stomach a simple intestine goes straight to outlet for the residue.

Each of the hard-shelled animals also has these parts, some more articulated, others less so. But each of them is more distinct in the larger animals. The spiral-shelled animals also have teeth that are hard and sharp, as was said previously,[195] with the fleshy part in between like in the soft-bodied animals and the soft-shelled ones. They also have the proboscis, as was said,[196] in between a sting and a tongue, and following the mouth a sort of bird-like crop, and following this a gullet; after this comes the stomach, in which is the so-called *mêkôn*, continuous with which is a simple intestine that has its starting-point from the *mêkôn*; for in all the shelled animals this residue, which seems to be especially edible, is present.

191. *HA* $524^{b}14–18$.
192. *HA* $524^{a}2–4$.
193. $654^{a}9–26$.
194. $678^{b}22–25$.
195. $678^{b}24$
196. $678^{b}13–15$.

The other spiral-shelled animals—for example, the purpuras and trumpet-shells—
15 are like the sea snails. But there are many kinds and forms of hard-shelled animals; for some are spiral-shelled, like the ones mentioned just now, some are bivalves, and some are univalves. In a way, though, even the spiral-shelled ones seem to be bivalves; for all animals of this sort have from birth an operculum over the visible part of the flesh for protection—for example, the purpuras, the sea snails, the nerites, and every
20 kind of this sort. For where the shell does not stand in front, it is easy for this part of the animal to be harmed due to external things striking against it. The univalves, due to being attached to something, preserve themselves by having their shell on their back, and by means of an alien protection become bivalves in a way—for example, the
25 so-called limpets; the bivalves—for example, the scallops and the mussels—do so by closing themselves up; and the spiral-shelled ones do so by means of this operculum,[197] as if becoming bivalves from univalves. But it is most of all the urchin that has a place of shelter; for its shell encircles it with a thick covering fortified with spines. Among
30 the hard-shelled animals, this is special to it, as was said previously.[198]

The nature of the soft-shelled animals and the hard-shelled ones is composed in the opposite way to that of the soft-bodied animals; for in the latter the fleshy part is outside, while in the former it is inside, and outside is the earthen part. The urchin, though, has no fleshy part at all.

35 All these animals and the other hard-shelled ones, as was said,[199] have a mouth, a tongue-like part, a stomach, and an outlet for the residue, though they differ in position and size. The way in which each of them has these parts must be observed
680ᵃ1 with the help of the *History of Animals* and the *Dissections*. For some things must be made perspicuous by reason, others more by observation.

Among the hard-shelled animals, the urchins and the so-called sea-squirt kind are
5 special. The urchins, for their part, have five teeth and between them the fleshy part, as in the case of all the animals mentioned, and following this a gullet, and after it the stomach, which is divided into many parts, as if the animal has many stomachs. For though they are separated and full of residue, they are attached to a single gullet
10 and end at a single outlet for the residue. Beyond the stomach, sea urchins have no fleshy part, as was said;[200] they have several so-called eggs, each in a separate membrane; and in a circle around the mouth are scattered certain black entities that are
15 nameless. Though there are several kinds (for there is not one form of all urchins), all of them have these parts; the so-called eggs are not edible in all of them, however, and are altogether small outside those of the common sorts. This is generally the case for the other hard-shelled animals as well; for their flesh too is not equally edible in
20 all cases, and the residue, the so-called *mêkôn*, is in some cases edible, in others not

197. 679ᵇ18.
198. Reference unclear.
199. 678ᵇ22–25.
200. 679ᵇ34.

edible. In the spiral-shelled animals, this is in the spiral, in the univalves in the base (for example, the limpets), and in the bivalves at the hinge.

In the bivalves the so-called egg is on the right side, while the outlet for the residue is on the other side. Those who call this part an "egg" do not call it so correctly; for this, like the fat in blooded animals, is present when they are thriving. That is also why it occurs during the seasons of the year—spring and fall—when they thrive; for in the cold and in hot spells all the hard-shelled animals suffer, and are unable to bear the excesses. A sign of this is what happens to the urchins; for right from birth they have these eggs, and more so during full moons, not because of feeding more, as some people think, but because the nights are warmer due to the light of the moon. For since they are sensitive to the cold because of being bloodless, they are in need of heat. That is also why in summer they are more thriving everywhere, except in the straits of Pyrrha; the ones there thrive no less in winter. The cause of this is that they are better supplied with food then, since the fishes leave the place during this season. **$680^{b}1$**

All the urchins have an equal odd number of eggs; for they have five, and the same number of teeth and of stomachs. The cause of this is that the egg, as was said previously,[201] is not an egg but a thriving condition of the animal. This so-called egg occurs only on one side in the hard-shelled animals;[202] and it is the same in the urchins too. Therefore, since the urchin is spherical, and not, as in the case of the body of the other hard-shelled animals, a single circle, and since the urchin is not circular in one dimension and not in another, but is so in all of them (for it is spherical), it is necessary for the egg too to be likewise. For there is not in the urchin, as in the others, a dissimilarity in its circularity. For the head is in the middle in all those; but this sort of part is up above in it. But its egg cannot be continuous; for it is not so in the others, but is on one side of the circle only. Therefore, it is necessary, since this part is common to all, while the spherical body is special to the urchin, for the eggs not to be even in number. For they would be diametrically opposed, because it is necessary to have one side like the other, if they were even and diametrically opposed. But if they were that way, the eggs would be on both sides of the circle. But this is not how it is in the other hard-shelled animals either; for it is on one side of their circumference that the oysters and the scallops have a part of this sort. Therefore, it is necessary that there be three, five, or some other odd number of eggs. But if they had three, they would be too far apart, but if more than five, they would be continuous; and of these, the first is not the better option, and the second is not possible. Therefore, it is necessary for them to have five eggs.

Due to the same cause, their stomach too is so divided, and the number of their teeth the same. For each of the eggs, since it is like a sort of body belonging to the animal, must necessarily have a likeness to its mode of life; for its growth is from

201. $680^{a}25$–27.

202. *Ostrea*, which also means "oysters," as at $680^{b}23$, seems here and at $680^{b}10$ and $^{b}22$ to have a more general meaning.

there. For since, if the stomach were one, the eggs would be too far away, or it would entirely occupy the cavity, so that the urchin would have difficulty moving and the container would not be full of nourishment; but since the interstices are five, it is necessary, since it is in each one, for the stomach to be divided into five. And due to the same cause, the number of teeth is also that many; for in this way nature can make the same assignment to the parts mentioned.

681ᵃ1 Why, then, the urchin has an odd number of eggs, and why just the number it has, has been stated; but of why some have altogether small ones, others large ones, the cause of this is that the latter are hotter in nature; for the hot is better able to concoct the nourishment, which is why the inedible urchins are more full of residue. And the hotness of their nature prepares them to be more mobile, so that they go grazing and do not remain sedentary. A sign of this is that urchins of this sort always have something on their spines, for they are frequently moving; for they use their spines as feet.

The sea squirts differ little from the plants in their nature, nonetheless they are more animal-like than the sponges; for these have altogether the capacity of a plant. For nature changes continuously from inanimate things to animals via those things that are alive though they are not animals in such a way that the one seems to differ altogether little from the other due to their closeness to each other.

The sponge, then, as was said,[203] by living only when it is attached, and ceasing to live when detached, is altogether like the plants. The so-called sea cucumbers and the lungs,[204] and further, certain other marine animals of this sort, differ a little from sponges in being detached; for none of them has perception, and they live as if they were detached plants. Even among the terrestrial plants, there are some sorts that both live and grow, some in other plants, others even detached, such as the one from Parnassus that some people call a "rock plant";[205] for it lives for a long time when hung up on pegs. And sometimes, even with the sea squirts, and any other kind of this sort there may be, which by living only when attached are much the same as a plant, but by having something fleshy would seem to have some perception, it is unclear on which side one is to put them. For this animal has two ducts and one vent, by which it takes in liquid as nourishment and in turn expels the leftover wet secretion; for it has no clearly perceptible residue, as the other hard-shelled animals do. That is why it is just to call this animal most of all, and any other of this sort there may be, "plant-like"; for none of the plants has any residue either. Through its middle there is a thin diaphragm, in which it is reasonable for what controls its life to belong.

Those that some people call "sea nettles" and others call "anemones" are not **681ᵇ1** hard-shelled animals, but fall outside the kinds resulting from division, and play a double game as both plant and animal in nature. For by being detached and falling upon their nourishment, and by perceiving what they fall upon, some of them are

203. 681ᵃ11–12.
204. *HA* 548ᵃ11.
205. Perhaps the houseleek.

animal-like. Further, they use the roughness of their body for their preservation. But by being incomplete, becoming quickly attached to the rocks, and by having no evident residue, though they have a mouth, they are much the same as the plant kind. Also similar to it is the starfish kind; for it too, after falling upon many of the hard-shelled animals, sucks their juice, and it is also like the detached animals mentioned—for example, the soft-bodied and soft-shelled ones. The same account also holds of the hard-shelled animals.

The parts concerned with nourishment, then, which are necessarily present in all animals, are the way we described, and clearly there must be some part, analogous to those present in the blooded animals, that controls the perceptual modalities; for this part must be present in all animals. But this part, among the soft-bodied animals, is a liquid situated in a membrane, through which the gullet extends to the stomach, that is attached more to the back, and is called the *mutis* by some people. There is another part of this sort in the soft-shelled animals too, and that one is also called the *mutis*. This part is liquid and body-like at the same time, and the gullet, as was just said, extends through the middle of it; for if it were between this part and the back, it would not be capable of taking on the degree of distension it does when nourishment enters, because of the hardness of the back. The intestine is on the outside of the *mutis*, and the ink is near the intestine, in order that it keep furthest away from the entrance and that what is disagreeable be far away from the better part and the starting-point. That this part is the analog of the heart, its place makes clear (for it is the same) and the sweetness of its liquid, inasmuch as it is concocted and bloodlike. In the hard-shelled animals, though the part in control of perception is the same way, it is less noticeable. However, in all those animals that are stationary this starting-point must always be sought around the middle, between the part that receives the nourishment and the part through which the secretion, either the spermatic one or the residual one, is produced, while in all the animals that move by walking, it must always be sought in the middle between the parts on the right and those on the left. **682^{a}1**

In the insects, the part in which this sort of starting-point belongs, as was said in the first accounts,[206] is between the head and the cavity around the stomach. In most of them this is one part, but in the rest it is more than one, as in those that are centipede-like and elongated. That is why they live when they are cut up. For nature tends in every case to make only one part of this sort, but when it is unable, it makes it actively only one, but potentially many. But this is clearer in some than in others.

The parts for nourishment are not alike in all insects, but exhibit much difference. For in some the so-called sting is inside the mouth, as if it were a combination that has at the same time the capacity of the tongue and of the lips. In those that do not have the sting in front there is a perceptual organ of this sort behind the teeth. Following this part in [pretty much] all of them is an intestine that is straight and simple up to the outlet for the residue; though in some this part has a spiral. Some have a

206. *HA* $531^{b}26$–$532^{a}5$, *Juv*. $468^{a}20$–$^{b}15$, $474^{b}1$–3.

stomach after the mouth, and from the stomach a spiraling intestine, so that those that are more voracious and larger in nature have a receptacle for a greater quantity of nourishment.

But among these, the cicada kind has the nature that is most special; for the same part has mouth and tongue united in one nature, through which, as through a root, it receives nourishment from liquids. All the insects, to be sure, are among the animals that take little nourishment, not so much because of their smallness as because of their coldness (for the hot needs nourishment and concocts the nourishment quickly, while the cold needs little nourishment), but most of all the cicada kind. For sufficient nourishment comes from the liquid left behind from the wind,[207] as with the ephemeral animals (these occur around the Black Sea), except that they live for a period of one day, while the cicadas live for more than one, though for few of them.

Since the internal parts present in the animals have been spoken about, it is necessary to return again to the remainder of the external parts. And it is necessary to begin with the animals that have just now been spoken about, and not from those where we left off,[208] so that from those that need less time spent on them, the account may have more time to spend on the complete and blooded animals.

4.6
The External Parts of the Insects

The insects among the animals are not numerously multipartite, but nonetheless exhibit differences in relation to each other. In fact, though, they are all many-footed, **682[b]1** because, relative to the slowness and coldness of their nature, their many-footedness makes their movement more rapid; and the most many-footed ones are the ones that become coldest due to their length—for example, the centipede kind. Further, it is because of having many starting-points that there are many sections[209] and many feet corresponding to these. All those that have fewer feet are flyers to compensate for the deficiency of feet.

Among the flyers, those whose mode of life is nomadic and who, because of their nourishment, must go from place to place, are four-winged and the bulk of their body is light—for example, the bees and the animals akin to these; for they have two wings on each side of the body. But those flyers that are small are two-winged, like the ant kind. And those that are light and have sedentary lives are many-winged like the bees, but have wing cases—for example, the cockchafers and insects of this sort—in order to preserve the capacity of their wings. For since they are sedentary,

207. Reading πνεύματος.
208. 3.2.
209. *HA* 487[a]32–34.

they are more easily destroyed than those that move easily, which is why they have a protection for these.

Their wing is unsplit and without a shaft; for it is not a feather-wing but a skin-like membrane, which, because of its dryness, of necessity detaches itself from the body when their fleshy part gets cold.

The insects have sections both due to the causes stated[210] and in order to save themselves from injury by curling up; for those that are elongated roll themselves up, and this could not occur in them, if they did not have sections. Those that do not roll themselves up make themselves harder by drawing their sections together. This becomes clear when they are touched—for example, in the case of the so-called dung beetles; for when they are frightened, they do not move, and their body becomes hard. And it is necessary for these animals to have sections; for it belongs in their substance to have many starting-points, and in this respect they are like the plants. For just like the plants, these animals when divided are also able to live; except that while these are able to do so up to a certain point, plant [sections] become complete in nature, that is, two or more plants come to be from one.

Some of the insects also have stings, for protection against those doing them harm. In some the sting is in the front, in others in the rear; in those that have it in the front, it is at the tongue; in those that have it in the rear, it is at the tail. For just as in the elephants the perceptual organ for odors has become useful both for strength and for purposes of nourishment, so in some of the insects the sting has been positioned at **683^{a}1** the tongue; for they both perceive the nourishment with this part and take it up and bring it to themselves.

All those whose sting is not in the front have teeth, some for eating, others to grasp nourishment and bring it to themselves—for example, the ants and all of the bee kind. All those whose sting is in the rear, because of their spiritedness, have the sting as a weapon. Some have their stings within themselves, like the bees and the wasps, because they are flyers; for since these stings are thin, outside they would be easily destroyed; while if the sting were prominent, as in the scorpions, it would provide them with a heavy load. (For the scorpions, though, since they are terrestrial animals and have a tail, it is necessary to have the sting on this, or else for it to be of no use for strength.) No two-winged insect has a sting in the rear. For it is because of being weak and small that insects are two-winged; for small animals are adequately lifted up by a smaller number of wings. And because of the same thing they have their sting in front; for since they are weak, they are just barely able to strike with things in front.

The many-winged insects, due to being larger in nature, are provided with a larger number of wings and have their strength in their rear parts. And it is better, if possible, not to have the same instrument for dissimilar uses, but rather the defensive one must be sharp, while the tongue-like one must be spongy and able to draw in the nourishment. For where it is possible for two things to be used for two works and not

210. $682^{b}4$–5.

impede each other, nature is accustomed not to make things as a blacksmith, with a view to economy, makes a spit-lamp; but where this is not possible, nature uses the same thing for more than one work.

Some of the insects—since, due to their hard eyes, they do not have exact sight—have long front feet in order that they can clear away things that fall in front of them with their front legs; which is precisely what both the flies and the bee-like kind appear to do; for they are always crossing their front legs. The back legs are longer than the middle ones both for walking and for ease in being lifted up from the earth when flying away. In all the jumping insects, this is yet more evident—for example, in the locusts and the flea kind; for when they bend and then extend [their back legs], it is necessary for them to be lifted up from the earth. The locusts do not have the rudder-like legs[211] in the front but in the back only. For it is necessary for the bend [in
683[b]1 these legs] to incline inward,[212] and none of the front limbs is of this sort. All insects of this sort are six-footed with the jumping ones included.

4.7
The External Parts of the Hard-Shelled Animals

The body of the hard-shelled animals is not multipartite. The cause of this is that they are stationary in nature; for it is necessary for the ones that are capable of movement to be more multipartite, because actions belong to them; for those participating in many actions need many instrumental parts. Among these animals, some are altogether immobile, while others participate in little movement; but nature, for their preservation, has put the hardness of their shells around them. Some of them are univalves, some bivalves, some spiral-shelled, as was said previously.[213] Among these, some have a spiral, like the sea snails, while others are just spherical, like the urchin kind. Among the bivalves, some open up—for example, the scallops and the mussels (for they are closed on one side, so as to open and close on the other); others are sealed on both sides—for example, the razor-fish kind.

All the hard-shelled animals, like the plants, have their head downward. The cause of this is that they get their nourishment from below, just as plants do by means of their roots. The result is, then, that in these the down parts are up and up parts down. They are within a membrane, through which they filter fresh water and get their nourishment. And though all have a head, the other parts of the body, besides the receptacle for the nourishment, are nameless.

211. *HA* 532[a]28–30.
212. I.e., toward the body.
213. 679[b]15–17, *HA* 4.4.

4.8
The External Parts of the Soft-Shelled Animals

The soft-shelled animals all move by walking, which is why they have numerous feet. There are four greatest kinds of them, the so-called crayfishes, lobsters, carids, and crabs. Of each of these there are many forms, differing not only in shape but also a lot in size; for some are large while others are altogether small.

Those that are crab-like and crayfish-like are similar in that both have claws. These they have not for the sake of progression, but for getting and holding, in place of hands. That is also why these bend in the contrary way to the feet; for the feet bend and twist toward the concave, the claws toward the circumference.[214] For in this way they are useful for grasping the nourishment to be carried toward the mouth. They differ in that the crayfishes have a tail, while the crabs do not have a tail; for, because **684^{a}1** they are swimmers, a tail is useful to the former (for they swim by leaning on their tails as on oars); but to the crabs it is of no use, because they live near the shore and in holes. All the crabs that are deep-sea dwellers have, because of this, feet that are much more unfit for progression—for example, the spider crabs and the so-called Heracleotic crabs—because they move little, but their preservation is attained by their being like the hard-shelled animals. That is why the spider crabs are thin-legged, the Heracleotic crabs small-legged.

The altogether small crabs that are caught among the small fishes have their back feet flat, in order that they be useful to them for swimming, since they have the feet as fins or oars. The carids differ from the crab-like animals in having a tail, and from the crayfish-like ones because they do not have claws; these they do not have because of having many feet; for [what should contribute to] growth at that place has been used up here. And they have many feet because they are no more swimmers than they are walkers.

The parts underneath and around the head in some cases are gill-like to take in and emit water; the lower parts are more laminar in the female crayfishes than the males; and the parts on the flap are hairier in the female crabs than the males, because they spread out their eggs on these, rather than expelling them, like the fishes and the other egg-layers; for since they are roomier and larger, these parts have more room for the eggs.

In all the crayfishes and the crabs, the right claw is larger and stronger; for all animals naturally do more with the parts on the right; and nature always assigns each thing either only or more so to those able to use it—for example, tusks, teeth, horns, spurs, and all the parts of this sort that are for protection and strength. The lobsters alone—both the males and the females—have one of the two claws larger, whichever one it happens to be. The cause of their having claws is that they are in the kind that

214. *IA* $704^{a}17$–$^{b}7$. The circumference is to be imagined as drawn around the body of the animal. Bending toward it is bending toward its convex part.

has claws, while they have this part in an irregular way because they are deformed, and
684ᵇ1 do not use it for what it is naturally for, but for progression.

As regards each of the parts, what their position is and what differences they exhibit in various animals, including in what way the males differ from the females, these must be observed with the help of the *Dissections* and the *History of Animals*.[215]

4.9
The External Parts of the Bloodless Animals

The internal parts of the soft-bodied animals were spoken about previously,[216] as also were those of the other animals. Externally, they have the trunk of the body, which is undivided,[217] and in front of this they have feet around the head, between the eyes, and around the mouth and teeth. The other animals with feet have them in the front and the back in some cases, in others coming out from the sides, like the many-footed bloodless animals. But this kind has them in a special way; for they have all their feet at the so-called front. The cause of this is that the back of these animals has been joined to their front, just like the hard-spiral-shelled animals.

For, in general, the hard-shelled animals are in one way like the soft-shelled animals and in another way like the soft-bodied ones; for in that the earthen part is outside and the fleshy part inside, they are like the soft-shelled animals; but in the way that the shape of their body has been composed they are like the soft-bodied ones; though this is so in a certain way for all of them, it is especially so for the spiral-shelled ones that have the [internal] spiral. For in both cases,[218] the nature [of the internal parts] is this way: if one considered it as a straight line, as it is in the case of the four-footed animals and the human beings, first, at the extreme upper point of this straight line is a sort of mouth, A, next the gullet, B, then the stomach, C; from this the intestine goes to the outlet of the residue, D. This, then, is the way it is in the blooded animals, and around this [straight line] are the head and the so-called thorax. As for the remaining parts, nature has added them for the sake of these [internal] parts and for the sake of movement—for example, the front limbs and the back ones. In both the soft-shelled animals and the insects, the straight course of the intestinal parts, at any rate, tends to be the same way [as in the blooded animals], though with respect to the motor services of the external parts they are different from the blooded animals.

The soft-bodied animals and the hard-spiral-shelled animals are much the same as each other, but the opposite way to these others. For the end-point has been bent
685ª1 around to the starting-point, as if, by bending the straight line, labeled E, one were to bring D close to A [Fig. 1].

215. *HA* 4.2–3, 5.7.
216. 4.5.
217. *HA* 527ᵇ8–10.
218. The hard-shelled animals and the soft-bodied ones.

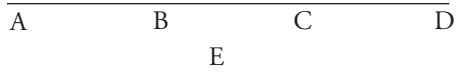

Fig. 1

For this is how the intestinal parts are in fact situated in the soft-bodied animals, and the cavity—which is called a "head" only in the case of the octopuses—is situated around them, while in the hard-shelled ones the spiral shell is like this. They do not differ in any other way, except that in the soft-bodied animals the surrounding part is soft, while in the others nature has put something hard around the fleshy part in order to preserve them, because of their difficulty in moving. That is why the residue, in both the soft-bodied animals and spiral-shelled ones, comes out near the mouth, except that in the soft-bodied ones it does so from below it, in the spiral-shelled ones from the side. It is due to this cause, then, that the feet of the soft-bodied animals are this way, and the contrary way to the others.

The cuttlefishes and the calamaries are unlike the octopuses because they are swimmers only, while the octopuses are also walkers. For the former ones have their legs above small, and, among these, the two outermost ones are the larger, while of the remaining ones, the two of the eight that are below are largest. For just as in the four-footed animals the back limbs are stronger, so in these animals the underneath ones are larger; for these support the weight and most of all move the animal. And the two outermost ones are larger than those in the middle because they collaborate with them. In the octopus, though, the four middle limbs are largest.

All these animals have eight feet, but the cuttlefishes and the calamaries have short feet, the octopus-like animals long feet. For the trunk of the body in the first ones is large, in the second ones small, so that in the second nature has taken away from the body and added to the length of the feet, while in the first, by taking from the feet, it increased the body. That is why in the second ones the feet are not only useful for swimming, but also for walking, while in the first ones they are useless for this; for their feet are small, but they have a large trunk. And since their feet are short and useless both for holding on to and not being dragged away from the rocks when there are waves and storms, and for drawing things to themselves from far away, because of these things, they have two long proboscises with which, mooring themselves, they lie at anchor like a ship, when there is storm, and by which the cuttlefishes and the calamaries hunt prey from far away and draw it toward themselves. The octopuses, though, do not have these proboscises, because their feet are **685^{b}1** useful to them for these things.

In all those animals that have suckers attached to their feet and tentacles, these parts have a capacity like that of the small plaited tubes with which the ancient doctors set fingers: they too have been plaited from fibers with which they draw in fleshy, yielding things. They surround them when they are relaxed; but when they tighten, they squeeze and hold on to everything touching them on the inside. So, since there

is nothing with which to draw things toward themselves other than feet in some and proboscises in the others, they have these parts for strength and other protection in place of hands.

The other octopuses have two rows of suckers, but one kind of octopus has one row. The cause of this is the length and thinness of their nature; for it is necessary for a narrow tentacle to have one row of suckers. It is not, then, because it is best that they have it, but because it is necessary due to the special account of their substance.

All these animals have a fin in a circle around the trunk. In the case of the other soft-bodied animals this is closed and continuous, as it is too in the case of the large calamaries. But in the smaller ones, the so-called small calamaries, this part is flatter and not narrow, as in the cuttlefishes and octopuses, and it starts from the middle and does not go all the way around in a circle. They have this part in order to swim and for steering, just like the rump feathers in the flyers and the tail fin in the fishes. But this part is smallest and least noticeable in the octopuses, because they have a small trunk and are sufficiently steered by their feet.

The internal and external parts of the insects, then, and of the soft-shelled animals, the hard-shelled animals, and the soft-bodied animals have now been spoken about.

4.10
The Remaining External Parts of the Blooded Live-Bearing Animals

It is necessary to investigate again from the start the blooded live-bearing animals, starting with the remainder of the previously mentioned[219] parts; once these have been distinguished, we will speak about the blooded egg-laying animals in the same way.

The parts around the head of the animals were spoken about previously,[220] and those around the so-called neck and the throat. All the blooded animals have a head; but in some **686ᵃ1** of the bloodless ones this part is indefinite—for example, in the crabs.

All the live-bearing animals have a neck, while among the egg-laying animals, some have one and some do not have one; for all those with a lung also have a neck, while those that do not draw breath from outside do not have this part. The head is mostly for the sake of the brain; for it is necessary for the blooded animals to have this part, and in a place opposite the heart, due to the causes stated previously.[221] And nature also placed some of the perceptual modalities on it, due to the blend of the blood being well proportioned, that is, suitable both for the heat of the brain and for the rest [from movement] and exactness of the perceptual modalities. Further, nature

219. 2.10–3.3.
220. 655ᵇ27–665ᵃ25.
221. 652ᵇ16–27.

has placed under it a third part, the one that crafts the incoming nourishment; for it is most fittingly situated there. For it was not possible for the stomach to be situated above the heart, that is, the starting-point, nor—being below the heart as it in fact is—was it possible for the entrance also to be below the heart; for the length of the body would be great, and the entrance would be very far from the starting-point of movement and of concoction.[222] The head, then, is for the sake of these things, while the neck is for the sake of the windpipe; for it is a shield, and it preserves the windpipe and the esophagus by encompassing them in a circle. Although in the other animals the neck is flexible and has vertebrae, the wolves and the lions have a neck consisting of a single bone; for nature had in view what was useful for their strength more than for other protections.

Following the neck and the head in these animals are the front limbs and the thorax. The human being, in place of front limbs and front feet, has arms and the so-called hands. For alone among the animals it stands upright, and this is because its nature and substance are divine, and the work of what is most divine is understanding and thinking; and this is not easy if a large part of the body is pressing down from above; for weight makes the movement of understanding and the common perceptual modality sluggish. That is why, when the weight and the corporeal part become too great, it is necessary for the body to incline toward the earth, so that for preservation's sake, nature put front feet under the four-footed animals in place of arms and hands. For it is necessary for all those animals that move by walking to have two back limbs, and animals of this sort became four-footed because their soul is unable to bear their weight. **686^{b}1**

For all the other animals are dwarf-like compared to the human being; for something is dwarf-like when its upper part is large, while the part that bears the weight and walks is small. The upper part is the so-called thorax, extending from the head to the outlet for the residue. In the human beings this part is proportional to the lower part, and in those who are completely grown it is much smaller; but when they are young the contrary is the case: the upper part is large, the lower one small. That is why they crawl and are unable to walk. And at first they do not even crawl, but rather do not move; for all children are dwarfs. But as human beings advance in age the lower parts grow, while in the four-footed animals the contrary occurs: the lower parts are largest at first, but as the animals advance in age they grow in the upper part, which is the cavity extending from the fundament to the head. That is also why foals are not at all, or only a little, smaller than horses in height, and why, when they are young, they are able to touch their head with their back limb, but are not able to when older. The solid-hoofed and cloven-hoofed animals are this way, while the hornless multi-split-footed animals, though dwarf-like, are less so than those; that is

222. The argument assumes that the mouth must be connected by an esophagus to the stomach above because the animal is live-bearing, and so it must have a neck and an esophagus (664^{a}20–25).

also why the growth of their lower parts in relation to the upper parts is in proportion to the deficiency [in their dwarf-likeness].

The bird kind, the fish kind, and every blooded kind are dwarf-like, as was said.[223] That is also why all animals are less practically wise than human beings. For even among human beings, children in comparison to grown men, and among the latter in their prime, the naturally dwarf-like—even if they have a surplus of some other capacity—are deficient in the possession of understanding. And the cause of this, as was said previously, is that in very many animals[224] the starting-point of the soul is sluggish and corporeal. Further, as the heat that raises becomes less and the earthen material becomes greater, the bodies of the animals also become smaller and many-footed, and in the end they become footless and stretch themselves out on the earth. Proceeding in this way a little further, even the starting-point they have is below, and the part corresponding to the head is incapable of movement and perception, and they become a plant, having the upper parts below, the lower parts above; for the roots of plants have the capacity of a mouth and a head, while the seed is the contrary; for it comes to be up above, on the uppermost shoots.

The cause, then, due to which some animals are two-footed, some many-footed, and some footless, and due to which some came to be plants and some animals, has now been stated, and why the human being is the only animal that is upright. And since it is upright in nature, it has no use for front limbs, but in place of these nature has provided arms and hands.

Anaxagoras said that it was because they have hands that the human beings are the most practically wise of the animals; it is reasonable, however, that it is because human beings are the most practically wise that they get hands. For the hands are instruments, and nature, like a practically wise human being, always distributes each instrument to the one able to use it. For surely it is more fitting to give pipes to someone who is a pipe player than to provide the one who has pipes with the craft of pipe playing; for nature has provided the lesser thing to the greater and more controlling one, not the more estimable and greater one to the lesser. If, then, it is better this way, and nature does the best of the things that are possible, it is not because it has hands that the human being is practically wisest, but because it is the most practically wise of the animals that it has hands. For the most practically wise animal would use the greatest number of instruments well, and the hand would seem to be not one instrument, but many; for it is, as it were, an instrument for instruments. To the one, then, able to acquire the most crafts, nature has provided the most useful of the instruments, the hand.

However, those who say that the human being is not well composed, but instead is the worst off of the animals (for it is, they say, barefoot, naked, and without weapons for strength), do not speak correctly. For the other animals have but one protection,

223. 686[b]2–5.

224. Reading πολλοῖς.

and cannot change it for another, but rather it is necessary for them to sleep and do everything as if they always had shoes on their feet, and never lay aside the shelter around their body, nor change whatever weapon they happen to have. For the human being, on the other hand, it is always possible to have many sorts of protection and to change them, and further, to choose what weapons to have, and to choose where **687ᵇ1** to have them. For the hand becomes a claw, talon, horn, spear, sword, and any other weapon or instrument whatever; for it will be all these due to being able to grasp and hold them all.

And for this the form of the hand has been appropriately contrived by nature. For it is divided and multi-split; for it is possible for a thing in a divided condition to be a compound, but not for a thing in a compound condition to be divided. And it is possible to use the hand as one, two, or many. Also, the joints of the fingers are well-disposed for grasping and squeezing.

One finger[225] is on the side of the hand, and is short and thick, not long [like the others]; for just as, if there were no hand at all, one could not grasp things, so too one could not grasp them if this finger were not on the side; for it squeezes from below upward, the others from below downward; and this must happen if, like a strong clamp, it is going to unite strongly, in order that, while being one, it may be equal to many. And it is short both because of strength and because it is of no benefit if it is long. Also, the last finger is rightly small, and the middle one long, like the middle oar of a ship; for it is above all necessary that what is grasped be encircled in the middle for the hand to do its work. It is because of this that it is called the "large finger," though it is small, because the other fingers are (one might almost say) useless without it.

The [form] of the nails has also been well contrived; for the other animals have nails for their use, while in the human beings they are a covering; for they are a protective cover for the fingertips.

The joints of the arms are—both for the bringing of nourishment to the mouth and for other uses—the contrary way to that in the four-footed animals. For in those it is necessary for the front limbs to bind inward; for they are used as feet, in order to be useful for progression; although, even among these animals, in the many-toed ones the front limbs tend to be useful not only for progression, but also in place of hands, as is in fact evident when they are being used; for they both grasp things and defend themselves with their front limbs. The solid-hoofed animals, by contrast, do **688ª1** so with their back limbs; for in them the front limbs do not have an analog of the elbows and hands. Some of the many-toed animals, because of this, have five toes on the front feet, but four toes on the back ones—for example, the lions, the wolves, and further, the dogs and the leopards; for the fifth toe is large, like the fifth finger on the hand. But the small many-toed animals have five toes on the back limbs as well,

225. I.e., the thumb.

because they are creepers, in order to grasp easily with their many nails and creep to a greater height, even overhead.

Between the arms in the human beings, and in the others between the front limbs, is the so-called chest. In the human beings it is broad, which is reasonable (for since the arms are situated on the side, they do not prevent this place from being wide), while in the four-footed animals, because of the forward extension of the limbs when they walk and change place, this part is narrow.

Because of this, the four-footed animals do not have breasts in this place; but in the human beings, because of the roominess of the chest and the need to shelter the parts around the heart, because of this, since the place is fleshy, the breasts have been differentiated. In the males they are fleshy due to the cause mentioned, but in the females nature has used them for an additional distinct work, precisely as we say it often does; for it puts away nourishment there for the offspring. There are two breasts because the parts are two, the left and the right. And they are harder, but separated, because the ribs are joined together in this place, and because their nature is not burdensome.

In the other animals, by contrast, it is impossible to have the breasts on the chest between the limbs (for they would impede progression); and they, in fact, have them in many ways. The few-offspring-bearing solid-hoofed horned animals have breasts between the thighs, and have two of these; the many-offspring-bearing or multi-split-footed animals in some cases have them around the abdomen and on the side, and have many—for example, the pig and the dog; in other cases, they have only two, around the mid-abdomen—for example, the lion. The cause of this
688b1 is not that it is few-offspring-bearing, since sometimes it gives birth to more than two, but that it does not produce much milk; for it uses up the nourishment it gets in its body, and it gets it rarely because it is carnivorous.

The elephant has only two breasts, and these are below the armpits of the front limbs. The cause of its having two is that it is one-offspring-bearing; of its not having them between the thighs, that it is multi-split-footed (for none of the multi-split-footed animals has them between the thighs); and of its having them up toward the armpits, that these are the primary breasts in those that have many breasts, and yield the most milk. A sign of this is what happens in the case of the pigs; for to the firstborn of the piglets they offer the primary breasts; hence, when the firstborn is the only one, it is necessary for it to have the primary breasts; and the ones below the armpits are primary. Due to this cause, then, the elephant has two breasts and in this place.

The many-offspring-bearing ones have them around the abdomen. The cause of this is that there must be many breasts for those that are going to rear many offspring; since, then, breadthwise it is impossible to have other than two, because the left and the right are two, it is necessary to have them lengthwise; and the place intermediate between the front limbs and the back limbs alone has length.

Those that are not multi-split-footed but are few-offspring-bearing or horned also have their breasts between the thighs—for example, the horse, the ass, the camel (for these are one-offspring-bearing, and while the first ones are solid-hoofed, the camel is cloven-hoofed), and again, the deer, the cow, the goat, and all the others of this sort. The cause of this is that growth in these animals is toward the upper part of the body. So where a collection and surplus of residue occurs (and this place is the one down and around the places of efflux), there nature has produced the breasts; for wherever a movement of the nourishment occurs, there too it is possible for the breasts to get it. In the human being, both the female and the male have breasts, while in the other animals some of the males do not have them—for example, some male horses do not have them, others (the ones that are like the mother) do have them.

The breasts have now been spoken about. After the chest is the place around the stomach, which is not enclosed by the ribs due to the cause stated previously,[226] in order that they do not impede either the expansion of the nourishment, which necessarily occurs when it is heated, or the uterus during pregnancy. At the end of the so-called thorax are the parts around the outlet for the residue, both liquid and dry.

Nature uses the same part for the outlet of the liquid residue and in regard to mating, alike in both the females and the males, in all the blooded animals, with a few exceptions, and in all the live-bearing ones. The cause of this is that the semen is something liquid and a residue; let this be assumed for now, later it will be proved.[227] It is the same way with the menses in the females, and the part with which the semen is emitted; these things too will be determined later; for now let it be assumed that the menses in the females are also a residue. The menses and the semen are both liquid in nature; so, that the excretion of things that are the same and alike is in these parts is in accord with the account.

How both the parts having to do with the seed and the parts having to do with the embryo are internally and in what way they differ are evident with the help of the *History of Animals*[228] and the *Dissections*, and will be stated later in the *Generation of Animals*.[229] But that the configurations of these parts has a necessary relation to their work is not unclear to perception. The instrument of the males exhibits differences in accord with the differences of the body; for not all are equally sinewy in nature.[230] Further, this part alone, without a change indicative of disease, increases and reduces in size; for of these, its increase is useful for copulation, its reduction for the use of the rest of the body; for if it were always in the same state, it would be an impediment. But this part is in its nature composed of things of this sort so that both changes can happen; for in part it is sinewy and in part cartilaginous, which is why it is able both to contract and have extension, and so be receptive of breath.

The female four-footed animals all urinate backward because this position is useful for mating, while a few of the males urinate backward—for example, the lynx, the lion, the camel, and the hare; but none that is solid-hoofed urinates backward.

689ᵇ1 The posterior parts and the parts around the legs in the human beings are special in comparison to the four-footed animals. Pretty much all of the latter have a tail, not only the live-bearing ones, but also the egg-laying ones; for even if this part is not large in those that have it, at any rate, they have as a token a sort of stump. The human being, on the other hand, though tailless, has haunches, while none of the four-footed animals does. Further, the human being also has fleshy legs, both thighs and shanks, while the others all have fleshless legs, not only the live-bearing ones, but all the animals that have legs; for they have sinewy, bony, or spinous ones. And of (one might almost say) all these things there is one particular cause, that the human being alone of the animals is upright. In order, then, for it to easily carry the upper parts, which are light, nature, by taking what is corporeal from the upper parts, added the weight to the lower ones; that is why it made the haunches fleshy as well as the thighs and the calves. At the same time the nature of the haunches is rendered useful for periods of rest; for standing is not wearying for the four-footed animals, and they do not get tired from doing this continuously (for, since they have four underlying supports, it is as if they continue to lie down), but for the human beings it is not easy to remain standing upright—on the contrary, their body has a need for resting and sitting.

The human being, then, has both haunches and fleshy legs due to the cause mentioned, and because of this is tailless (for the nourishment that is carried there is used up on these parts, and because of having haunches, the use for which a tail is necessary is removed), while in the four-footed and the other animals it is the contrary; for since they are dwarf-like, all the weight and all that is corporeal is situated in the upper part, having been removed from the lower ones. That is why they are without haunches and have long legs. And in order for the part that serves as the outlet of the residue to be guarded and in a protective shelter, nature has provided them with the so-called caudal appendage or tail, by taking the nourishment that is produced in the legs. But the ape, because its shape plays a double game, and is neither of these and also both, has neither tail nor haunches because of this: as being two-footed, it has no tail; as being four-footed, no haunches. Among the so-called
690ª1 tails, however, there are many differences, and nature uses these too for additional purposes, not only for a protection and covering for the fundament, but also for the benefit and use of their possessors.

The feet in the four-footed animals differ; for some of them are solid-hoofed, some cloven-hoofed, and some multi-split-footed. They are solid-hoofed in all those animals in which, because of their size and of having much earthen material, in place of horns and teeth, this sort of part receives a secretion into the nature of the nail, and because of its abundance, in place of many nails, there is one, the hoof.

Because of this they also lack a knucklebone, for the most part, because the presence of a knucklebone makes bending the back leg more sluggish; for limbs with one joint straighten and bend more quickly than those with many, while the knucklebone, since it is a fastener,[231] is like an alien limb put between the two, adding weight while also making the step more stable. For it is because of this, in fact, that those animals with a knucklebone do not have a knucklebone in the front limbs but in the back ones, because the leading ones must be nimble and easy to bend, while there must be stability and elasticity in the back ones. Further, for defense, the knucklebone makes the blow heavier; and animals of this sort use their back limbs for kicking what is hurting them. The cloven-hoofed animals, though, do have a knucklebone (for their back limbs are lighter), and because they have a knucklebone they are also not solid-hoofed, since the bony material left out of the foot remains in the joint. But the multi-split-footed animals do not have a knucklebone; for then they would not be multi-split-footed, but rather the foot would be split only for as much of its breadth as the knucklebone extends over. That is also why most of those that have one are cloven-hoofed.

The human being has the largest feet of all the animals for its size, and reasonably so; for it alone stands upright, so that since they, being two, are going to bear all the weight of the body, they must have both length and breadth. Also, the size of the digits is contrariwise in the feet and in the hands, which is in accord with the account; for the work of the hands is to grasp and squeeze, so that the digits must have length (for the hand grasps with the part that bends), while that of the feet is to walk stably, so that the unsplit part of the foot must be considered as corresponding to these digits. And it is better that its extremity be split rather than unsplit; for otherwise the entire foot would suffer together if one part were harmed, but since it is divided into toes, this does not happen to the same extent. Further, since they are short, the toes are also less liable to injury; that is why the feet of the human beings are multi-split, not long-toed, and have the nail kind due to the same cause as in the hand; for the extremities must be especially protectively covered because of their weakness.

Pretty much all the blooded live-bearing terrestrial animals have now been spoken about.

4.11
The Egg-Laying Animals

Among the blooded egg-laying animals, some are four-footed, others footless. But only one kind among these is footless, that of the snakes. The cause of their being footless was stated in the studies concerned with determining the modes of animal

231. 654b21.

progression.[232] In other respects they are much the same in shape as the four-footed egg-laying animals.

These animals have a head, and the parts on it, due to the same causes as in the other blooded animals, and a tongue in their mouth, except for the river crocodile; this animal seems not to have one, but the place alone. The cause of this is that in a way it is at once terrestrial and aquatic: because it is terrestrial, it has a place for a tongue; because it is aquatic, it is tongue-less. For among the fishes, as was said previously,[233] some seem not to have a tongue, unless one opens their mouth very wide, while others have an unarticulated one. The cause of this is that there is little use for a tongue in these animals because it is not possible for them to chew or taste, but rather it is in swallowing that the perception and the pleasure of the nourishment occur in all these animals. For while the tongue produces the perception of flavors, the pleasure of solid foods occurs in swallowing; for it is when they are being swallowed that oily, hot ones and others of this sort are perceived. The live-bearing animals also have the same perception—indeed, the enjoyment of pretty much the majority of gourmet dishes and solid foods occurs due to the expansion of the esophagus during swallowing. That is why those that are intemperate concerning drinkable things and flavors are not the same as those that are intemperate concerning gourmet dishes and solid food, but though in the other animals the perception of flavor is also present, in those animals,[234] as it were, [only] the other perception[235] is.

Among the four-footed egg-laying animals, the lizards, like the snakes, have a divided tongue with a tip that is altogether hair-like, as was said previously.[236] The seals also have their tongue divided; that is also why all these animals are gluttonous. The four-footed egg-laying animals are also sawtoothed, just like the fishes. All their perceptual organs are like those of the other animals—for example, of smell, nostrils, of sight, eyes, and of hearing, ears (except not sticking out, but the duct only, just like the birds). The cause in both cases is the hardness of the skin; for the birds are feathered, while all these animals are hard-scaled; and the scale is, as regards its region, the same as the soft scale, but is in nature harder. This is clear in the case of the turtles, the large snakes, and the river crocodiles; for their scales become stronger than their bones, implying that this is their nature.

These animals[237] do not have the upper eyelid, as the birds also do not, but instead close their eyes with the lower one, due to the cause mentioned in the case of the birds.[238] Some of the birds also blink with a membrane that comes from the corners of the eyes, but these animals do not blink; for they are harder-eyed than the birds.

232. *IA* 708ᵃ9–20.

235. See *EE* 1231ᵃ12–17.
236. 660ᵇ6–10.
237. The four-footed egg-laying ones.
238. 657ᵇ4–7.

The cause of this is that, for the birds, sharp-sightedness is more useful for their mode of life, since they are flyers, but for these animals it is less useful; for all animals of this sort are hole-dwellers.

Since the head is divided in two, the upper part and the lower jaw, the human being and the live-bearing four-footed animals move the jaws up, down, and to the side, while the fishes, the birds, and the egg-laying four-footed animals move them up and down only. The cause of this is that this sort of movement is useful for biting and cutting, that to the side for grinding. For those, then, that have molars, movement **691ᵇ1** to the side is useful, but for those that do not, it is not at all useful; that is why it is excluded in all animals of this sort; for nature produces nothing superfluous. Though all the other animals move their lower jaw, the river crocodile alone moves the upper one. The cause of this is that it has feet that are useless for grasping and holding; for they are altogether small. For these purposes, then, in place of feet, nature has made a mouth that is useful to it. But for holding or grasping, it is from whichever of the two directions the blow would be stronger, that it is more useful for the jaw to be moved; and it is always stronger from above than from below. Since, then, the use of the mouth is for both grasping and biting, and its use for seizing is more necessary for an animal with neither hands nor feet naturally well suited for it, it is more useful for these animals to move their jaw from above than from below.

Due to the same cause crabs also move the upper part of their claw, not the lower; for it is in place of hands that they have claws, so that the claws must be useful for grasping, not for cutting. Cutting and biting are the work of teeth. In the crabs, then, and in all the other animals that are able to do their seizing at leisure because of not using their mouth in the water, cutting and grasping are divided, that is, they grasp with hands and feet, while they cut and bite with the mouth. But in the crocodiles nature has made the mouth useful for both things, by having the jaws move in this way.

All animals of this sort also have a neck, because they have a lung; for they breathe through the windpipe, which is long. And since the part between the head and shoulders has been called the "neck,"[239] among animals of this sort, the snake would seem least of all to have a neck, but rather an analog of the neck—at any rate, if it is in terms of the extremes just mentioned that one must determine this part. In comparison to animals of the same kind, it is special to the snakes to be able to turn their head to the rear while the remainder of the body is at rest. The cause of this is that, **692ᵃ1** like the insects, they are able to roll up, inasmuch as their vertebrae are flexible and cartilaginous. Of necessity, then, due to this cause, this happens to them, but also for the better, for the sake of protection against being harmed from behind; for being long and footless they are naturally unsuited both for turning around and keeping watch on things coming from behind; for it is of no benefit to be able to raise their head, but be unable to turn it.

239. *HA* 493ᵃ5.

Animals of this sort also have a part analogous to the chest. But they do not have breasts, either there or on the rest of the body; none of the birds or fishes does either. The cause of this is that none of these animals has milk; and the breast is a receptacle and, as it were, a container for milk. Nor do these animals, nor any of the other non-internally egg-laying ones, have milk; this is because they lay eggs; and it is in the egg that the milky nourishment present in the live-bearing animals is produced. These things will be talked about more perspicuously in the studies concerning generation.[240] About the bending of the joints common to all animals[241] there was a previous investigation in the *Progression of Animals*.[242]

Animals of this sort also have a tail, longer in some, shorter in others; we stated the universal cause of this previously.[243] The chameleon is the thinnest of all the egg-laying terrestrial animals; for it has the least blood of all. The cause of this is the character of its soul; for because of fear it becomes multiform, and fear is a cooling due to a want of blood and a deficiency of heat.

As regards the blooded animals, then, both footless and four-footed, what all their external parts are, and due to what cause each is present, has pretty much been stated.

4.12
The Birds

Among the birds, differences from each other lie in the excess and deficiency of their parts, that is, are in accord with the more and less. For some of them are long-legged, others short-legged, some have their tongue broad, others, narrow, and it is the same way with the other parts. Taken in isolation, they differ little from each other in their parts, but in comparison to the other animals they differ even in the shape of their parts.

They are all feathered, and this is special to them in comparison to the others; for the parts of the [egg-laying] animals are in some cases hard-scaled, in others soft-scaled, while the birds are feathered. Also, their wing is split and not alike in form to that of the whole-winged animals;[244] for in some animals it is unsplit, in others split, and the unsplit wing is without a shaft, while the split wing has one.

They also have on the head the extraordinary—and special in comparison to the others—nature of the beak. For while in the elephants there is a trunk[245] in place of the hands, and in some of the insects a tongue in place of a mouth, in the birds

240. *HA* 5.33–34, 6.1–15, *GA* 3.1–7.

244. The insects.
245. 658[b]35.

there is a beak in place of teeth and lips. The perceptual organs were spoken about previously.[246]

They have a neck that by nature extends [from the body], due to the same cause as the other animals do;[247] in some this is short, in others long, pretty much following along with the legs in most cases. For those that are long-legged have a long neck, while those that are short-legged have a short one, the web-footed ones aside; for if it were short in those with long legs it would not be of service to them for feeding from the earth, nor if it were long in those with short legs. Further, for flesh-eaters length would be contrary to their mode of life; for a long neck is weak, while for them life comes from overpowering. That is why none of the crook-taloned birds has a long neck.

The web-footed ones and those that have divided feet that are, however, turned up like a snub nose, because they are not of the same kind as the web-footed ones, have a long neck (for a neck of this sort is useful for getting nourishment from the water), but legs that are short for swimming.

Their beaks also differ in accord with their modes of life. For some have a straight beak, others a curved one: it is straight in all those in which it is for the sake of nourishment, curved in the carnivorous; for one of this sort is useful for overpowering, and it is necessary for their nourishment to be procured from live animals. But all those whose mode of life is marsh-dwelling and herbivorous have a broad beak; for a beak of this sort is useful for digging, and for drawing in and cropping the nourishment. Some birds of this sort have a long beak, just as also a neck, because of getting their nourishment from the depths. And many birds of this sort that are also web-footed, either unconditionally or in part,[248] live by hunting some of the small animals that live in the water; and for birds of this sort the neck becomes just like a fishing rod, while the beak becomes like a fishing line and hook.

The back and the underneath part of the body, which is called the "thorax" in the four-footed animals, is a naturally unified place in the birds. For attached to this, in place of[249] arms and front feet, they have feathered wings, a part special to them; that is why, in place of a shoulder blade, the extremities of the wings are on the back. They have two legs, as in the human being, though bending inward, as in the four-footed animals, not outward, as in the human being; their wings, like the front limbs of the four-footed animals, bend toward the circumference.[250]

They are two-footed of necessity; for the substance of the bird is that of the blooded animals, but at the same time winged, and blooded animals do not move by means of more than four points.[251] The attached parts, then, are four, as they are in

246. 2.12–13, 16–17, *HA* 4.8.
247. 691ᵇ26–28.
248. 694ᵇ2–5.
249. Reading ἀντὶ.
250. 683ᵇ35.
251. *HA* 490ᵃ26–30.

the other terrestrial animals that move by walking, and also in the case of the birds; but while four arms and legs are present in the former, in the birds, in place of front limbs or arms, there is something common to them, [feathered] wings (for in virtue of these they are able to stretch out [and fly], and being able to fly is included in the substance of the bird), so that it remains for them to be of necessity two-footed; for in this way they will move, with their wings included, by means of four points.

All birds have a chest that is pointy and fleshy: pointy, for flight (for broad ones, in pushing a large quantity of air, move with difficulty); fleshy, because what is pointy is weak, if it does not have much protection. Under the chest is the stomach, which goes to the outlet for the residue and the leg joints, just as in the four-footed animals and the human beings. These, then, are the parts that are between the wings and the legs. All animals that are live-bearing or egg-laying have an umbilical cord during generation, though when the birds are grown it is not noticeable. This is made clear in the studies concerning generation.[252] For the umbilical cord becomes united with the intestine, and is not, as in the live-bearing animals, a part of the blood vessels.

Further, some of the birds are flyers and have wings that are large and strong—for **694ᵃ1** example, the crook-taloned ones and the carnivores; for it is necessary for them to be flyers because of their mode of life, so that for the sake of this they have a mass of feathers and their wings large. But it is not only the crook-taloned ones that are flyers, but also all the other kinds of birds whose preservation lies in the swiftness of their flight or that are migratory. Some birds, though, are non-flyers, but are heavy: those whose mode of life is to stay on the ground and that are grain-eaters or else are swimmers and spend their life around water. The bodies of the crook-taloned birds, wings aside, are small, because the nourishment is used up for their wings, that is, for their weapons and their means of defense; in the non-flyers, on the contrary, the bodies are bulky, which is why they are heavy.

Some of the heavy birds have, as a means of defense in place of wings, so-called spurs on their legs. But the same birds do not at the same time come to have both spurs and be crook-taloned; the cause of this is that nature produces nothing superfluous. And for those that are crook-taloned and flyers spurs are useless; for it is in ground combat that they are useful; that is why they are present in some of the heavy birds. And in these crook-talons would not only be useless but also harmful, since by getting stuck in the ground, they are contrary to progression. That is also why the crook-taloned birds walk with difficulty and do not settle on rocks; for the nature of their talons is contrary to both.

It is of necessity that this occurs during generation; for the hot earthen material in the body becomes parts useful for strength. For when flowing upward it produces either hardness or largeness of the beak, while if it flows downward, it produces strong spurs on the legs, or talons on the feet, that are large and strong. But it does not produce each of these in distinct places at the same time; for if it were spread

252. *HA* 6.3, *GA* 752ᵃ24–ᵇ12, 753ᵇ14–754ᵃ20.

around, the nature of this residue would become weak; but, in some cases, it furnishes length for the legs; in some, in place of these things, it fills in the intermediate **694ᵇ1**
spaces in their feet. And it is because of this that the swimmers among the birds are necessarily web-footed, some unconditionally web-footed, while others, though they have the nature of the particular toes divided, they have something added to each of them like an oar which is, as a whole, continuous. Of necessity, then, these things 5
occur due to these causes; but it is because of what is better for the sake of their mode of life that they have feet of this sort, in order that, since they live in water, and wings are useless, they will have feet useful for swimming. For they become like oars for sailing and[253] fins for the fishes; and that is why if the fins of the latter, or what is 10
between the toes of the former, are ruined, they can no longer swim.

Some of the birds are long-legged. The cause of this is that the mode of life of the birds of this sort is marsh-dwelling; for nature produces the instruments for the work, not the work for the instruments. That is why, then, since they are not swimmers, they are not web-footed, and why, because of spending their life on spongy ground, they are long-legged and long-toed, and most of them have many 15
joints in their toes. And since they are not flyers, but all birds are composed of the same matter, when the nourishment used up on the rump of the other birds goes into the legs, they grow. That is why in flight they use these in place of the rump; for, when they fly, they stretch the legs out to the rear; for in this way they 20
are useful to them, while otherwise they would impede them. But some birds fly while keeping their short legs next to their abdomen; for in these birds the feet do not impede them in that way, and in the crook-taloned ones they also advance the work of grasping prey. 25

Among the birds with long necks, those with a thicker one fly with the neck stretched out, while those with a thin and long neck fly with it bent up; for because of this protective shelter the neck is less easily broken if they fly into something.

All the birds have a haunch, though in such a way that they would seem not to **695ª1**
have one but rather two thigh bones, because of the length of the haunch; for it extends to the middle of the abdomen. The cause of this is that this animal is two-footed, but not upright, so that if indeed it had—as in the human beings and the four-footed animals—a haunch extending a short distance from the fundament, and the leg immediately next to it, it would be unable to stand upright. For the human 5
being is upright, while in the four-footed animals the front limbs serve as supports for their weight. But the birds, because of being dwarfish in nature, are not upright, and do not have front limbs (because of this they have wings in place of these); and in place of this nature has, by making the haunch long, fixed it firmly in the middle 10
of the body, and placed the legs under there, so that with the weight well-balanced on either side, they are able to walk and to stand still.

253. Reading καὶ.

The cause, then, due to which they are two-footed while not being upright has been stated. The cause of their legs being fleshless is the same as in the case of the four-footed animals, which was also spoken about previously.[254]

Every bird, split-footed and web-footed alike, is four-toed. (For about the fact that the Libyan ostrich is cloven-hoofed we will speak later,[255] and, at the same time, about the rest of the ways in which it is contrary to the bird kind.) Three of these toes are in the front, while one is behind for stability, in place of a heel. Among the long-legged birds, this toe is deficient in size—for example, in the case of the *krex*.[256] But they do not have a greater number of toes. In the other birds, the position of the toes is like this; the wryneck[257] alone has two in the back and two in the front. The cause of this is that its body is less inclined forward than that of the others.

All the birds have testicles, but they have them internally; the cause will be stated in the *Generation of Animals*.[258]

695[b]1 The parts of the birds, then, are this way.

4.13
The Fishes

The fish kind is yet more docked in the front parts. For they have neither legs, nor hands, nor wings (the cause of these things was stated previously[259]), but their entire trunk is continuous from the head to the tail. The tail is not alike in all of them, but while some have much the same one, some of the broad fishes have one that is spinous and long. For growth from there is produced in the broad part, as is the case in the torpedo fishes, the stingrays, and any other selachians of this sort there may be. Among fishes of this sort, then, the tail is spinous and long, but in some it is fleshy and short, due to precisely the same cause as in the torpedo fishes; for it makes no difference whether the tail is short with more flesh or long with less flesh. In the case of the fishing frogs[260] the contrary occurs; for because of their broad front part not being fleshy, the quantity of fleshy material nature takes away from there, it adds to its back part and the tail.

The fishes do not have separate limbs, because their nature in accord with the account of their substance is to be swimmers, since nature produces nothing that is either superfluous or pointless. And since, in accord with their substance, they are blooded, it is because of being swimmers that they have fins, and because of not being

254. 689[b]6–15.
255. 4.14.
256. *HA* 609[b]9.

260. *HA* 487[a]27.

terrestrial that they do not have feet; for the addition of feet is useful for the movement on land. And it is not possible to have, at the same time, four fins and two feet, or any other limb of this sort; for they are blooded. The water newts, though, while they have gills, have feet; for they do not have fins, but a tail that is open-structured and broad.

Those fishes that are not broad (as the ray and the stingray are) have four fins, two on the back parts and two on the underneath parts. None of them has more than this; for then they would be bloodless. Pretty much all of them have the fins on the back part, but some of those that are long and thick do not have those on the underneath parts—for example, the eel and the conger eel, and the kind of mullet found in the lake in Siphae. All those that grow even longer and are more snake-like, like the muraena, have absolutely no fin, but move by bending, using the water as the snakes do the land; for snakes swim in precisely the way that they crawl on the ground. The cause of the snake-like fishes not having fins is precisely that of the snakes being footless. (The cause was stated in the studies concerning the progression and movement of animals.[261]) For otherwise, if they moved by means of four points, they would move badly; for they would move with difficulty either if they had the fins near each other or if they had them far apart, because of the distance between them. But if their points of movement were more [than four], they would be bloodless. And the cause is also the same in the case of the fishes that have only two fins; for they are snake-like and longer, and use bending in place of the two fins. That is why they crawl on dry ground too and live a long time, and some do not immediately gasp for breath, while those that are akin to terrestrial animals do so less.

696^{a}1

As for the fins themselves, the fishes that have only two fins have them on the back parts (all those not prevented from having them because of their breadth). Those having fins near the head have them because of not having length in that place, by means of which, in place of fins, they will move; for it is at the tail that the body of fishes of this sort is elongated. But the rays and the fishes of this sort, in place of fins, swim by means of their broad extremity.

The torpedo fish and the fishing frog have the fins on the back parts down below because of the broad part above, while those on their underneath parts are near the head. For this does not prevent the broad part from being moved; but to compensate for the breadth of the part above, these are smaller than those on the back. The torpedo fish has its two fins near the tail; but in place of the two [other ones] it uses the broad part of each of its semicircles as two fins.[262]

The parts of the head and the perceptual organs were spoken about previously.[263] The fish kind has as a special part, in comparison to the other blooded animals, the

261. *IA* $708^{a}9$–20.
262. *IA* $709^{b}16$–19.
263. $658^{a}3$–10 (eyes), $659^{b}14$–16 (nostrils), $660^{b}11$–$661^{a}6$ (tongue), $662^{a}6$–15 (teeth), $662^{a}31$–33 (mouth).

696[b]1 nature of the gills; due to what cause was stated in the studies concerning respiration.[264] Also, some of those with gills have covers for the gills, but all the selachians (for they are cartilaginous) are without coverings. The cause of this is that the former are spinous, and the coverings are spinous, but the selachians are all cartilaginous. Further, the movements of these are sluggish due to their being neither spinous nor sinewy, while those of the spinous ones are quick; and the movement of the gill cover must occur quickly; for the nature of the gills is, as it were, for exhalation. That is why, in the selachians, the closure of the ducts of the gills is produced by the gills themselves, and there is no need of a covering in order for it to occur quickly.

Some of the fishes have many gills, others few, some have double gills, others simple ones; but in most the last one is simple. For exactness about these, one must observe them with the help of the *Dissections* and the *History of Animals*.[265] The cause of the number of gills being larger or smaller is a larger or smaller amount of heat in the heart; for the movement must be quicker and stronger in those with more heat. And those with more gills and double gills have a nature of this sort more than those with simple and fewer gills. That is also why some of them (those with fewer and less strong gills) are able to live out of the water for a long time—for example, the eel and all those that are snake-like; for they do not need much cooling.

The fishes also exhibit differences as regards the mouth. For some have the mouth straight across and toward the front, while others have it in the underneath parts—for example, the dolphins and the selachians; and they turn the underneath parts up to seize their nourishment. And nature appears to do this not only for the sake of the preservation of the other animals (for since these fishes are slowed down during the turn the others save themselves; for all fishes of this sort are carnivorous), but also so that they are not guided by their greediness where nourishment is concerned; for if they could grasp it more easily, they would be destroyed because of being filled up too quickly. In addition, the nature of the snout, since it is round and narrow, cannot open easily.

697[a]1 Further, among those that have the mouth up above, some have a mouth that opens wide, others a tapering one: all the ones that are carnivorous have a mouth that opens wide, like the sawtoothed ones, because strength for fishes of this sort lies in the mouth; but all those that are not carnivorous have a tapering one.

As for the skin, some of them have a scaly one (but the scale stands off from the body because of its brightness and thinness), others a rough one—for example, the angelfish and the ray, and the fishes of this sort; but fewest in number are the smooth-skinned ones. The selachians have skin that is scale-less but rough, because of their being cartilaginous; for nature has used up the earthen material from the cartilage on the skin.[266]

264. *Juv.* 476[a]1–16.
265. 504[b]28–505[a]20.
266. 655[a]23–34.

None of the fishes has testicles, either external or internal, nor does any other of the footless animals, which is why the snakes also do not. But the same duct is for the residue and for what has to do with generation, just as in all the other egg-laying four-footed animals, because of their not having a bladder or producing liquid residue.

The fish kind, then, differs in these ways from the other animals.

As for the dolphins, the whales, and all the cetaceans of this sort, they do not have gills, but a pipe, because they have a lung; and the seawater taken in through the mouth is discharged through the pipe. For it is necessary for water to be taken in because they get their nourishment in water, and when it has been taken in, it is necessary to discharge it. Gills are useful for those animals that do not breathe, due to what cause was stated in the studies concerning respiration;[267] for it is impossible for the same animal to breathe and have gills at the same time; instead, for the discharge of water these animals have a pipe. It is situated in front of their brain; for otherwise it would be separated from their spinal column. And the cause of these animals having a lung and breathing is that the large animals need more heat in order to move. That is why the lung in them is full of blood heat. These animals are in a way terrestrial and aquatic; for they take in air like terrestrial animals, but are footless and get their nourishment from water like the aquatic ones.

The seals and the bats, because they play a double game, in the one case, as both **$697^{b}1$** aquatic and terrestrial, in the other, as both flyers and terrestrial—because of this, participate in both and neither. For the seals as aquatic have feet, while as terrestrial they have fins (for their back feet are altogether fish-like, and further, all their teeth are saw-like and sharp); the bats as flyers have feet, but as four-footed they do not; and they have neither a tail nor a rump: because of being flyers, no tail; because of being terrestrial, no rump. This occurs in bats of necessity; for they are skin-winged, and nothing has a rump unless it is split-feathered; for the rump is produced from a feather of this sort. And a tail would be an impediment if it were present among the feathers.

4.14
The Libyan Ostrich

The Libyan ostrich is also the same way; for it is in some respects like a bird, and in some like a four-footed animal. For as not four-footed it has feathers, and as not a bird it does not rise up in flight; in fact, its feathers are not useful for flight, but are hair-like. Further, as four-footed it has upper eyelashes, and it is bald around the head and above the neck, with the result that it has hairier eyelashes; but as a bird its lower parts are feathered; and it is two-footed like a bird, but cloven-hoofed like a four-footed animal; for it does not have toes, but hooves. The cause of this is that its

267. *Juv.* $476^{a}1$–16.

size is not that of a bird but of a four-footed animal. For it is necessary, speaking in universal terms, for birds to be as small as possible in size; for it is not easy for a body of great mass to be moved up off the ground.

As regards the parts, then, due to what cause each is present in the animals has been stated about all of animals individually. These matters having been determined, the next thing is to go through those having to do with their generation.

ON THE MOVEMENT OF ANIMALS*

De Motu Animalium

1
The Internal Points of Rest

As regards the movement of animals, what belongs to each kind of them, what their differences are, and also what the causes are of each of the coincidents that belong to them, all this was investigated elsewhere.[1] What must now be investigated, in general, is the common cause of their moving with any movement whatsoever; for some animals move by flying, others by swimming, some by walking, and some in some other such ways. **698ª1** 5

What moves itself by itself is the starting-point of other movements, of this the starting-point is what is unmoved, and the first mover is necessarily unmoved—this was determined previously[2] in dealing with eternal movement, when it was determined whether or not there is such a thing, and if there is, what it is.[3] But this must be grasped not only by means of universal accounts, but also in the case of the particular and perceptible things because of which we also seek those universal accounts, and which we believe these accounts must fit. For it is evident in these cases too that movement is impossible if there is nothing at rest, in the first place within the animals themselves; for it is always the case that if one part moves, another is at rest, and it is because of this that animals have joints. For they use their joints like the center [of a circle] and the whole part in which the joint is located becomes both one and two, straight and bent, changing [between being them] potentially and actively because of the joint. When it is bending and moving, one point in the joint moves while another remains at rest, just as if geometrical points A and D [Fig. 1] on the diameter were to remain at rest, while point B moved, and [the line] AC comes to be. 10 15 20

* Translated by Andrea Falcon. Text: O. Primavesi et al., *Aristotle: De Motu Animalium. A New Critical Edition of the Greek Text* (Oxford, 2023). Oliver Primavesi generously granted permission to use the diagrams produced for that edition. The correct place for this treatise, which deals with what is common to body and soul (*DA* 433ᵇ19–21), is immediately following *Div. Somn.*

2. *Ph.* 8.5.
3. *Ph.* 8.1–2, 8.8.

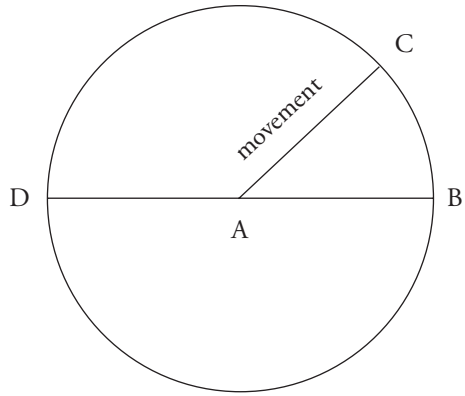

Fig. 1

But in this case the center seems to be in every way indivisible (for in fact move-
25 ment is, as they say, a "fabrication" in such cases; for none of the mathemati-
cal objects moves), whereas the points in the joints come to be now potentially
one but actively divided, now actively one but potentially divided. But then the
698[b]1 starting-point against which [there is movement],[4] insofar as it is a starting-point,
always remains at rest when the lower part moves. For example, when the forearm
moves, the elbow remains at rest; when the whole arm moves, the shoulder remains
at rest; when the leg moves, the knee remains at rest; and when the whole leg
moves, the hip remains at rest. It is evident, then, that each animal must also have
5 something within itself that is at rest, from which the starting-point of what moves
will be, and by supporting itself against which the animal will move all at once both
as a whole and in part.

2
The External Point of Rest

But any rest within the animals is nonetheless ineffective, unless there is something
outside that is unconditionally at rest and unmoved, and it is worth pausing to inves-
10 tigate what has been said; for it makes our theoretical investigation extend not only to
animals but also to the movement—that is, the spatial movement—of the universe.[5]
For just as there must be something unmoved within the animal, if it is to move, even
more so there must be something unmoved outside it, supporting itself against which
15 what is moved moves. For if something always gives way, as it does with "a mouse

4. 698[b]6.
5. Cf. *EE* 1248[a]24–29.

in pitch,"[6] or as it happens with people who try to walk on sand, the animal will not advance, nor will there be any walking if the ground does not stay still, nor any flying or swimming if the air or the water does not exert counterpressure. And it is necessary that this be something other than what is moved, and the whole other than the whole—that is, what is unmoved in this way must be no part of what is moved. Otherwise what is moved will not be moved.

Evidence for this is the following puzzle: Why is it that one moves a boat with ease when one pushes it with a pole from outside, hitting the mast or some other part of it, but when one tries to do this while being in the very same boat, one would not move it, not even if one were Tityus or Boreas blowing from within the boat (if he happened to be trying to sail in the way painters make him do; for they paint him as blowing the wind from within the boat)? For whether one blows out the breath **699ª1** gently or violently so as to produce a very strong wind, or whether it is something other than breath that is blown or pushed out, first, one must push while supporting oneself against some part of oneself that is at rest, and, second, that very part, or the whole thing of which that happens to be a part, must stay put, resting on something that is external. But that someone who is pushing the boat while standing in the boat and supporting oneself against the boat does not move the boat is reasonable, because it is necessary for what one is supporting oneself against to stay put. And in this case it happens that what one tries to move and what one supports oneself against are the same. But if one pushes and pulls the boat from outside, one moves it; for the earth is no part of the boat.

3
Heavenly Movement

But one might raise the following puzzle: If something moves the whole heaven,[7] must there be something unmoved, and must this be neither any part of the heaven, nor in the heaven? For if it moves the heaven while itself moving, it must move it while touching something that is unmoved, and this must be no part of the mover; or if the mover is from the outset unmoved, it will be likewise no part of what is moved. And, at any rate on this front, those who say that no part whatsoever of the sphere [of the heaven] that moves in a circle is at rest are right; for it would be necessary either for the whole of it to remain at rest or for its continuity to be torn apart. But in thinking that the poles have some capacity, though they have no magnitude but are just limits and points, they are not correct. For in addition to the fact that nothing of this kind has any substance, it is also impossible for a single movement to be caused by two movers; but they make the poles two things. It is from going through this

6. A proverbial expression. The pitch gives way under the mouse, so that it has nothing to support itself on to climb out.
7. I.e., the universe.

puzzle that one might conclude that there is something that is related to the whole of nature in the way the earth is related to the animals that move of themselves.

Those who in a myth-like way make Atlas put his feet on the earth would seem to have told their story from the thought that he is like an axis and rotates the heaven around its poles. And this would be in accord with reason because the earth remains at rest. But for those who offer this account it is necessary to say that the earth is no part of the universe. And in addition, the strength of what moves must be [at least] equal to that of what remains at rest. For there is a certain amount of strength and capacity in virtue of which what is at rest remains at rest, just as there is an amount in virtue of which the mover causes movement. And as there is, of necessity, some proportion for contrary movements, so there is too for states of rest. And movements and states of rest that are equal are unaffected by each other, but are mastered in accord with the excess [of either one]. That is why the mover within the universe, whether it is Atlas or any other thing of this sort, must not exert more counterpressure than the stability that the earth requires to stay put. Otherwise, the earth will be moved away from the center, that is, from its own place. For as the thing that pushes pushes, so the thing that is pushed is pushed, and with equal force. But it is the thing that was earlier at rest that causes movement, so its strength must be even greater than, rather than similar or equal to, its state of rest. And likewise with respect to what is moved without causing movement. So the capacity of the earth in its state of rest will have to be as great as the capacity that the whole heaven combined with what moves it has. But if this is impossible, it is also impossible for the heaven to be moved by something of this sort from within.

4
A Closely Connected Puzzle

But there is also a puzzle about the movements of the parts of the heaven, which one might want to investigate because it is closely related to what has just been said. For if someone were to overcome with his capacity for movement the state of rest of the earth, he would obviously move the earth away from the center. And the strength from which this capacity derives is clearly not unlimited, for the earth is not unlimited either, so neither is its weight. But since things are said to be impossible in many ways (for we do not say that it is in the same way impossible for a sound or human beings on the moon to be seen; for the sound is of necessity invisible, but the human beings, although of such nature as to be seen, will not be seen) the following puzzle arises: we think that the heaven is, of necessity, incapable of passing away or of being dissolved, but according to this account it is not so out of necessity. For it is natural and possible that there is a movement greater than the capacity in virtue of which the earth remains at rest, and greater than the capacity in virtue of which the fire and the

body above[8] move. If, then, these prevailing movements do exist, those bodies will be destroyed by one another. And if these movements do not exist, but it is possible for them to exit (for it is not possible for the movement to be unlimited because it is certainly not possible for a body to be unlimited[9]), it would be possible for the heaven to be dissolved. For what prevents this from happening, if indeed it is not impossible? But it is not impossible, if its opposite is not necessary. But about this puzzle let there be a separate account.[10]

[To resume where we left off:] Must, then, there be something unmoved and at rest outside what is moved, which is no part of it, or not? And must this also be so in the case of the universe? For it would perhaps seem absurd if the starting-point of the movement were within. That is why, to those who think in this way, the following would seem to be well said by Homer:

> But you could not drag from the sky down to earth
> Zeus, the highest counselor, not even if you worked very hard
> Take hold, all you gods and all goddesses.[11]

For what is entirely unmoved cannot possibly be moved by anything. Herein also lies the solution to the puzzle just mentioned, as to whether it is possible or not for the arrangement of the heaven to be dissolved if it depends on an unmoved starting-point.

But in the case of animals not only must there be what is unmoved in this way, but also, within those that move with respect to place—all those that move themselves—there must be something by supporting itself against which the one that is moving will move. For one part of the animal must be at rest and another in movement, as when it moves one of its parts; for one part supports itself against another as against something that is at rest.

As regards the inanimate things that move, one might be puzzled as to whether they all have within themselves something at rest and something that moves, and whether they too must support themselves against some external thing that is at rest, or whether this is impossible for something such as fire, earth, or any other of the inanimate things, but is true only of the things by which, as first movers, these are moved. For all inanimate things are moved by something else, and the starting-point of all that is moved in this way are the things that move themselves. Among such things, animals have already been spoken about.[12] All such things must have what is at rest both in themselves and outside themselves, [the latter being something] against which they support themselves. But whether there is something that is higher

8. The heaven.
9. *Ph*. 3.5.

12. Chapters 1 and 2.

and is a first mover is unclear, and concerning a starting-point of this sort there is separate account.[13] But all the animals that move do so by supporting themselves against things that are external to them, even when they breathe in and breathe out. For there is no great difference between throwing a weight that is great or small, which is just what those who spit and cough, and those who breathe in and those who breathe out, do.

5
Extending the Account to Qualitative and Quantitative Change

Must there be something at rest only in what moves itself by itself with respect to place, or also in what alters itself by itself and in what grows? (Concerning coming to be from the start and passing away there is a separate account.[14]) If the first movement is the one we claim it is,[15] this should be the cause of coming to be and passing away, and presumably of all other sorts of movement. And just as in the universe, so too in the animal movement with respect to place is the first movement, provided the animal has reached maturity, so that movement with respect to place is also the cause of growth, if the animal ever comes to be itself a cause by itself, and also of alteration. But if it does not, this is not necessary. The first phases of growth and alteration come to be due to something else and through other things, and there is no way in which it is possible for anything to be, for itself, the cause of coming to be and passing away. For the mover must precede the moved, and the generator the generated, and nothing is prior to itself.

6
The Moving Factors of the Animal

As regards the soul, whether it is moved or not, and if it is moved, how it is moved, was spoken about previously in our determinations concerning it.[16] But since all inanimate things are moved by something else, and since it was determined earlier, in our writings on first philosophy,[17] in what manner the first and eternally moved thing is moved and how the first mover moves it, it remains to grasp theoretically how the soul moves the body, and what is the starting-point of animal movement. For of all other things, except for the movement of the universe, the animate things are the cause of movement (at least, of those that do not move one another by striking

13. *Met.* 12.7–10.
14. I.e., *GC*.
15. I.e., movement with respect to place. See *Ph.* 260b29–261a26.
16. *DA* 1.3–4.
17. *Met.* 12.7.

against each other). That is also why all the movements of these things have a limit; for the movements of the animate ones do too. For all animals cause movement and move for the sake of something, so that this is the limit all of their movement, the for-the-sake-of-which.

But we see that the movers of the animal are thought, perception, imagination, deliberate choice, wish, and appetite. All these can be reduced to understanding and desire. For both imagination and perception hold the same place as understanding; for they all are capable of discerning, although they differ from one another in the ways discussed elsewhere.[18] And wish, spirit, and appetite are all forms of desire, and deliberate choice has a share in both thought and desire. As a result, the object of desire and the intelligible object are the first things to cause movement—not any intelligible object, though, but only the end of things doable in action. That is why, among goods, what causes movement is a thing of this sort, and not just any noble thing; for it is insofar as something else is done for the sake of this, and insofar as it is the end of the things done for the sake of something else, that it causes movement. And one must posit that the apparent good holds the same place as the good, and also the pleasant; for the latter is an apparent good. So it is clear that, in one respect, the thing that is eternally moved by the eternal mover and also each of the animals are moved in a similar way, but that in another respect, they are moved in distinct ways. That is also why the former is eternally moved, whereas the movement of animals has a limit. And what is eternally and truly noble, that is, what is primarily good (and not good at one time but not at another), is too divine and too estimable to be [so] relative to something else.

The first thing, then, causes movement without being moved, but desire and the desiring part cause movement by being moved. But it is not necessary for the last of the moved things to cause movement to anything. It is also evident from these considerations that it is reasonable that the spatial movement of the things moved is last in the chain of events; for the animal moves and progresses due to desire or deliberate choice, when some alteration has taken place in accord with perception or imagination.

7
How the Animal Moves

How is it that, when one understands, sometimes one acts but sometimes one does not, and sometimes one moves but sometimes one does not? It seems that a similar thing also happens in thinking and making deductions about unchanging things. But there the end is a piece of theoretical knowledge (for when one understands the two premises, one has also understood and put together the conclusion), while here the

18. *DA* 3.3–5.

conclusion resulting from the two premises becomes the action. For example, when someone understands that every human being should take a walk, and that he is a human being, immediately he takes a walk; or when he understands that no human should take a walk now, and that he is a human being, immediately he remains at rest. And he does both these things if nothing prevents him [in the one case] or if nothing forces him [in the other]. "Something good must be produced by me; a house is a good thing"; immediately, he produces a house. And "I need covering; a cloak is covering; I need a cloak; what I need I must produce; I need a cloak"; he produces a cloak. And the conclusion, that a cloak must be produced, is an action. He acts, though, from a starting-point: "if there is to be a cloak, then this thing must happen first; but if this thing, then that thing"; and that thing he does immediately. It is clear, then, that the action is the conclusion. But the premises, those that can result in production, come to be through two routes, both through the good and through the possible.[19]

Just as with those who ask dialectical questions, so thought does not at all stop to investigate the other premise, the obvious one. For example, if it is good for a human being to walk, he does not waste time by lingering on the fact that he is human. That is why what we do in action without rational calculation we do quickly. For whenever someone is active either with perception, with imagination, or with understanding, in relation to the for-the-sake-of-which, what he desires he immediately does. For in place of asking questions or thinking, the activation of desire comes about. Appetite says: "I must drink"; "This is drinkable," says perception (or imagination or understanding); immediately, he drinks. In this way, then, animals are impelled to move and to act, with desire being the last cause of their movement, and this arises either through perception, imagination, or understanding. Of the animals that desire to act, some produce or do things in action because of appetite or spirit, others because of deliberate choice or wish.

701b1 Just as the automata move [even] when a small movement has occurred, when the cables are released and the [figures immediately] clash against one another with their [swords]), and when the little wagon that the rider tries to move in a straight line [again] and again, and yet the wagon moves in a circle due to the unequal size of its wheels (for the smaller becomes like a center as in the case of cylinders)—so too do animals move. For they have instrumental parts of this sort: the nature of the sinews and the nature of the bones, the bones corresponding to the pegs and the iron in the example, the sinews to the cables, and when the sinews are released and the bones slackened, animals move. However, in the case of the automata and in the little wagons there is no alteration taking place (since if the inside wheels were to become smaller and then larger again, the same thing would move in a circle). But in the case of the animals the same thing can become both larger and smaller and can

19. I.e., the end (or for-the-sake-of-which) and what the agent can do to further it.

also change its shapes when the parts increase in size and contract due to heat, breath, and cold, and undergo alteration.

Alteration, though, is caused by imaginations, perceptions, or understandings. For perceptions immediately entail their being alterations of a certain sort, while imagination and understanding have the capacity of their objects. For in a certain way the intelligible form of what is either hot or cold, pleasant or frightening, is in its being exactly like each of the relevant things. That is why we shudder and are frightened [even] when we merely grasp these things with the understanding. All such things are affections and alterations. As alterations take place, some parts in the body become greater while others smaller. And that a small change occurring at a starting-point also makes great and numerous differences down the road is not difficult to see—for example, when the rudder shifts a tiny little bit, the change in the direction of the prow is considerable. Further, whenever in virtue of heat or cold or some other affection of this sort an alteration takes place in the region around the heart, or in an imperceptible part within it, this makes a considerable difference in the body, causing episodes of blushing and paleness, of shivering and trembling, and their contraries.

8
Looking for the Internal Starting-Point of Animal Movement

The starting-point of movement, then, as was said,[20] is the object of pursuit and avoidance in the sphere of what is doable in action. But of necessity heating and cooling follow the understanding and the imagination of those things (for what is painful is to be avoided, while what is pleasant is to be pursued). Although this escapes notice when it happens around small parts, pleasant and painful things are pretty much always accompanied by some cooling and heating. This is clear in the case of **702[a]1** affections. For feelings of confidence, fear, sexual arousal, and other bodily affections, both pleasant and painful, are accompanied by heating and cooling—sometimes in a part, and sometimes in the entire body. But memories and expectations too, using affections of this sort as images, are causes of these things, sometimes to a lesser, sometimes to a greater extent. So it is reasonable that the internal parts—those situated in the areas around the starting-points of the instrumental parts—are crafted as they are so as to change from being solidified to liquid and from liquid to being solidified, and to alternate between soft and hard.

Since these things happen in this way, and since what can be affected and what can affect are of such a nature as we have often stated,[21] whenever it happens that there is what can affect and what can be affected, and neither one fails to fulfill its account,

20. 700[b]23–25, *DA* 431[a]9–14.
21. Most notably in *GC* 1.7–9.

then immediately the one affects, and the other is affected. Because of this at the same time, so to speak, someone understands that he must walk, and starts walking (if nothing else impedes him). For the affections suitably prepare the instrumental parts, desire prepares the affections, and imagination prepares the desire. But imagination comes to be through either understanding or perception. And this happens immediately and quickly because what can affect and what can be affected are among the things that are related to each other by nature.

But what first moves the animal must be located in some starting-point. And it has already been stated[22] that the joint is the starting-point of something and the end-point of something else. That is why nature employs the joint in a way as one thing and in a way as two things. For whenever [the animal] is moved from there, it is necessary for one of the end-points to remain at rest and for the other to be moved (for that what moves must support itself against something that is at rest was stated previously[23]). The end-point of the forearm,[24] then, is moved and does not cause movement. Instead, one part in the joint of the elbow causes movement and is moved, namely, the part in the whole thing itself that is moved. But there must also be something that is unmoved, which is what we mean by saying that the elbow is potentially one but in activity becomes two. So if the forearm were the animal, it is somewhere there[25] that the movement-causing starting-point of the soul would be.

But since it is also possible for some of the inanimate things to stand in this relation to the hand, for example, if someone were to cause movement to the stick in his hand, it is evident that the soul should be in neither one of the end-points, neither in the end-point of what is moved nor in the other end-point (for the wood too has both a starting-point and an end-point in relation to the hand). So, because of this, **$702^{b}1$** at any rate, if the movement-causing starting-point from the soul is not located in the stick, it is not located in the hand either; for the extremity of the hand[26] is in the same relation to the wrist, and this part is in the same relation to the elbow. For parts that are attached naturally are in no way different from those which are not; for the stick becomes like a detachable part. Therefore, it is necessary for the movement-causing starting-point of the soul to be in none of the starting-points that are also end-points of something else, not even when there is something else more external than that—for example, the end-point of the stick has its starting-point in the hand, and the end-point of the latter has it in the wrist. But if the starting-point is not located in the hand because it is still higher up, it will not be located in the wrist either; for when the elbow is at rest, all that is below the elbow, and is a continuous part with it, is still moved.

22. $698^{a}16–21$.

24. I.e., the wrist.
25. I.e., the elbow.
26. I.e., where the hand joins the stick.

9

The Location of the Soul as the Internal Support of Animal Movement

But since the [movement of the animal] is similar from the left and from the right sides, and since contraries are moved at the same time, so that the left is not moved in virtue of the right being at rest, nor the right in virtue of the left being at rest, and the starting-point is always in something higher than both, it is necessary for the movement-causing starting-point of the soul to be in the middle; for the middle is the end-point for the end-points on both sides. And this is the same with respect to the movements from above and from below (for example, the ones from the head) as well as with those proceeding from the backbone, in those animals that have a backbone. And this is reasonable; for we say the perceptual part is also there, so that when, because of perception, the region around this starting-point is altered, and changes, the parts next to it are changed along with it, expanding and contracting, so that of necessity, because of these things, movement comes about in the animals.

The middle part of the body is potentially one, but actively it must become more than one. For it is both the case that the limbs are moved from the starting-point at the same time, and also the case that one is moved while the other is at rest. I mean, for example, in ABC [Fig. 2],

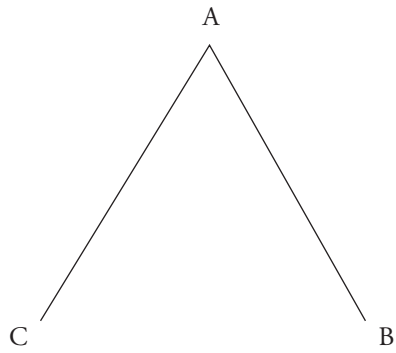

Fig. 2

B is moved, and A causes movement. But there must be something at rest if one is to be moved and the other is to cause movement. Therefore A, being potentially one, will be two in activity, so that necessarily it is not a geometrical point but some magnitude. But it is possible that C too is moved at the same time as B, so that necessarily both starting-points in A cause movement while being moved. Therefore, there must be something else beyond these, something that moves and is not moved. For

the extremities, that is, their starting-points that are in A, would support themselves against each other while they are moved, just as if two human beings were to move **703a1** their legs by supporting themselves on each other's backs. But what moves both must be one, and this is the soul, which is something other than such a magnitude but present in it.

10
Innate Breath

In accord with the account that states the cause of an animal's movement, desire is the intermediate item, the one that causes movement while being moved; and in animate bodies such a thing must be a body. What is moved, then, but is not of such a nature as to cause movement can be affected by an alien sort of capacity; but it is necessary for what causes movement to have some capacity and strength. But all animals manifestly have innate breath and are strengthened by it. In which way the innate breath is preserved was stated elsewhere.[27] But this seems to be related to the soul-involving starting-point[28] as the point in the joints that causes movement and is moved is related to the point that is unmoved. And since the [soul-involving] starting-point is located for some animals in the heart, and for others in its analog, because of this the innate breath too is manifestly located there. But as for the question of whether the breath is always the same or is always changing, let that be for a separate account (for the same question arises about the other bodily parts[29]).

It is evident that breath is naturally well-disposed to be capable of causing movement and supplying strength. And the works of the movement are pushing and pulling, so that the instrument must be capable of being expanded and contracted. And such is the nature of breath; for, since it is contracted and expanded without force, it is capable of pushing and pulling by force due to the same cause. And it has weight in relation to what is fiery and lightness in relation to what is its contrary. What is going to cause movement without [undergoing] alteration must be of this sort; for the natural bodies master each other in accord with their excess: the light is overpowered and brought down by what is heavier, and the heavy is overpowered and brought up by what is lighter.

By means of which moving bodily part the soul causes movement, and due to which cause, has now been stated. But one must suppose that the animal is constituted like a city that is in good legislative order. For once order is implanted in the city, there is no need for a separate monarch who must be present at each of the things that come about, but rather each individual performs his own task as prescribed, and one thing happens after another because of habit. In the animals the very same thing

27. No such focused discussion is extant. *De Spiritu* (*On Breath*) is not by Aristotle.
28. *GA* 737^a7–12, 762^a20, 766^b12–14.
29. *GA* 726^b22–24.

happens because of their nature and the fact that each part is naturally constituted so as to do its own work. So there is no need for soul in each of them, but rather it is situated in some bodily starting-point, and the other bodily parts live by being naturally attached to that, and do their own work because of their nature. **$703^{b}1$**

11
Involuntary and Non-voluntary Movements

How animals move with voluntary movements, then, and due to which causes, has now been stated. However, some of their parts move with involuntary movements, but mostly with non-voluntary ones. I call "involuntary" the movement of the heart and that of the sex organ; for they often move when something appears, although the understanding has not ordered them to do so. And I call "non-voluntary" sleep, awakening, breathing, and all the others of this sort that there are. For neither imagination nor desire are unconditionally in control of any of these. But rather, since it is necessary for animals to undergo natural alteration, and since it is necessary for some of the parts being altered to expand and for others to contract, so that already they are moved and changed with changes that are by nature alternating (and the causes of these movements are heating and cooling, both those from outside and those which are by nature internal), the movements that happen contrary to reason[30] also happen in the parts just mentioned when the relevant alteration has taken place. Understanding and imagination, as was said previously,[31] supply what is capable of producing the relevant [bodily] affections; for they supply the forms of the things that are capable of producing them. And among the parts, the heart and the sex organ most make this clear, because each of them is like a separate animal. The cause of this is that they possess the liquid that is characteristic of life.[32] In the case of the heart, the cause due to which it is so is evident; for it possesses the starting-points of perceptions. But there is a sign that the generative part is of this sort as well; for the capacity of the seed too comes out of it, like a sort of animal.

It is reasonable that the movements go to the starting-point from the parts and to the parts from the starting-point. And in this way the parts also reach each other. One should understand A as a starting-point. Then with respect to each of the letters of the diagram [Fig. 3], the movements proceed *to* the starting-point and *from* the starting-point that is moving and changing, since it is potentially many: the starting-point of B proceeds to B, the starting-point of C to C, and the starting-point of both to both. But the movement proceeds from E to C by going from E to A *as to* the starting-point, and from A to C *as from* the starting-point.

30. $703^{b}7–8$.
31. $701^{b}16–22$.
32. *Ph*. $255^{a}6$, *GA* $733^{a}11$, $761^{a}27$.

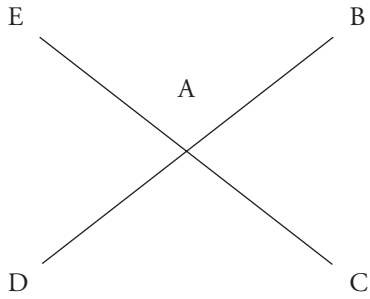

Fig. 3

As for the fact that when one understands the very same things, the movement contrary to reason sometimes occurs, and sometimes does not, the cause is that sometimes the affectable matter[33] is present, but sometimes it is not present in the suitable
704^{a}1 quantity or quality.

As regards the parts of each animal, as regards soul, and further as regards perception,
704^{b}1 sleep, memory, and the common movement, we have given the causes; it remains to speak about generation.

33. I.e., the matter that is receptive of the form coming from the understanding.

ON THE PROGRESSION OF ANIMALS*

De Incessu Animalium

1
What Is to Be Explained

As regards the parts that are useful to animals for movement with respect to place, one must investigate due to what sort of cause each part is such as it is and for the **704ª5** sake of what it belongs to them, and also the differences in the parts of one and the same animal and compared to the parts of animals different in kind.

But, first of all, let us grasp how many issues are to be investigated. One of these is what the fewest points are by means of which animals move; then, why blooded animals move by means of four points, bloodless animals by means of more than four; and, in general, why some animals are footless, some two-footed, some four-footed, and some many-footed, and why, as many as have feet have an even number of them. More generally, why the points by means of which animals move are even in number.

A further issue is due to what sort of cause the human being and the bird are two-footed while the fishes are footless, and why the human being and the bird, although they are two-footed, have contrary bendings of their legs. For the human being bends its leg toward the circumference,[1] the bird toward the concave, and the human being bends its legs and arms in contrary directions with respect to itself: arms toward the concave while knees toward the circumference. And the four-footed live-bearing animals bend their legs in the contrary ways with respect to human beings, and also in contrary ways with respect to themselves: they bend front legs toward the convex part of the circumference, back legs toward the concave part. Further, those four-footed **704ᵇ5** animals that are not live-bearing but egg-laying bend their legs in a way special to them, that is, laterally and away from their body. An additional issue is due to what cause the four-footed animals move their legs diagonally.

One must get a theoretical grasp on the causes of all of the above facts, and on the causes of any other similar facts; for *that* things are this way is evident from the investigation of nature, but *why* they are this way must now to be investigated.

---

* Translated by Andrea Falcon. Text: P. Golitsis in A. Falcon and S. Stavrianeas (eds.), *Aristotle on How Animals Move* (Cambridge, 2021).

1. The circumference is to be imagined as drawn around the body of the human being. Since Aristotle contrasts bending toward the circumference and bending toward the concave, we can take "toward the circumference" as an abbreviation for "toward the convex part of the circumference."

2
Explanatory Starting-Points

We begin our investigation by positing those [starting-points] that we are accustomed to use often in our methodical inquiry into nature, assuming that things occur in this manner in all nature's works.

One of these [starting-points] is that nature does nothing pointlessly, but always does what is best from among the available possibilities for the substance of each kind of animal. That is why if it is best in a certain way, it is also this way in accord with nature.

Further, one should grasp how many and what sort of dimensions of magnitude are present in what sorts of animals. There are six dimensions but three pairs: the first is the up and the down, the second is the front and the back, and the third is the right and the left.

In addition, one should grasp that the starting-points of movement with respect to place are pushing and pulling. These are, then, intrinsic movements, whereas what is carried by something else is moved coincidentally; for what is carried by something else does not seem to move itself but rather to be moved by something else.

3
External Supporting Point and Internal Complexity

With these determinations in place, let us speak about the issues that come next in order. Some of the animals that change with respect to place do so by means of their whole body all at once, like the jumpers, others by means of their parts, like each of the animals that moves by progression. In both these cases of change, what moves always changes while supporting itself against what is beneath it. That is why when this thing gives way too quickly for what is making its movement on it to support itself, or when it offers no resistance at all to what is moving, then nothing can move itself on it. For even the jumper makes its jump both while supporting itself against its own upper part and against what is under its feet; for its parts offer some resistance to one another at the joints—and, more generally, what presses presses against what is pressed. (That is why pentathletes jump further with weights than without, and runners run faster if they swing their arms; for a sort of support is generated in the extension of the arms toward the hands and the wrists.)[2]

What moves always makes its change by using at least two instrumental parts: the first, as it were, compressing, and the second compressed. The part that remains still is compressed because of the carrying, while the part that is raised is extended

2. In the extension of the arms there is some support of the forearms on the hands.

by carrying the weight. That is why nothing that is without parts can move in this way; for it does not have the division between what is to be acted upon and what is to act on it.

4
Dimensions

The dimensions by which animals are naturally determined are six in number: the up and the down, the front and the back, the right and the left. Further, all living beings have the up and the down, for the up and the down are found not only in animals but also in plants. But the up and the down are distinguished by [their] work, and not only with respect to their position relative to the earth and the heaven. For where the distribution of nourishment and growth is from in each, this is the up; and where it, ultimately, comes to an end, this is the down. For the one is a sort of starting-point, **$705^{b}1$** the other a sort of end-point; and the up is a starting-point. And yet in the case of plants, at any rate, the down might seem to be the more proper one; for the up and down do not have the same position in them as in animals. But though in relation to the universe they do not have the same position as in the animals, with respect to their work they are the same. For the roots are the up for plants; for it is from the roots that the nourishment is distributed to what grows, and it is by means of them that the plants get it, just as the animals do by means of their mouth.

As to the things that are not only alive but also animals, to all things of this sort the front and the back belong. For they all have perception, and it is in accord with it that the front and the back are determined; for the parts in which perception is naturally present and from which it derives, these are the front, while the opposite parts are the back.

Those animals that not only have a share in perception but are also able to make a change with respect to place by themselves, in addition to the dimensions already enumerated, are determined by the left and the right. Like those discussed earlier, each of them is distinguished by work rather than position; for the starting-point in the body from which change with respect to place by nature derives is the right in each animal, while what is opposite to this, and naturally follows its lead, is the left.

The distinction between the right and the left is more articulated in some animals than in others. For those that use instrumental parts (I mean feet, wings, or any other such part) to make the change mentioned have the aforesaid distinction more clearly articulated around these parts. Those that do not use such parts but proceed by making divisions in their bodies, as do a few of the footless animals (for example, snakes, the caterpillar kind, and also the so-called earthworms) have the division mentioned, though not as perspicuously.

A sign that the starting-point of movement is from the right is also the fact that all human beings carry loads on their left shoulder; for in this way it is possible for what

carries the load to be moved, while the mover is set free. That is also why it is easier to
706ᵃ1 hop on the left leg; for the right is naturally the mover, and the left the moved. So the load too has to be placed not on the mover but rather on the moved; if it were placed on the mover and the starting-point of movement, either it would not be moved at all or it would be moved with greater difficulty. A sign that the right is the starting-point
5 of movement is also the way in which people advance; for they all lead with the left parts, and after standing still, put the left parts forward in preference, unless it is done otherwise by luck; for they move not with the part they put forward but with the one with which they step off; also, they defend themselves with the right parts.

Due to this cause too the right parts are the same in all animals; for the starting-
10 point from which movement derives is the same for all of them, and has its position in the same place in accord with nature. The right is indeed the starting-point from which movement derives, and that is why the spiral-shelled animals have their shells on the right; for they do not move in the direction of the spiral, but they all proceed
15 in the opposite direction; for instance, the purpuras and the trumpet-shelled animals. Since, then, all animals move from their right parts, and the right part moves in the same direction as the animals themselves, it is necessary for all animals alike to be right-sided.

Human beings have their left limbs detached more than any other animal because, among animals, they are most in accord with nature; and by nature it is also better
20 for the right to be separated from the left. That is also why the right limbs are most right in human beings: since the right limbs are separated, it is reasonable that the left limbs should be less easy to move and most detached in them. The other starting-points too are most in accord with nature and most separated in the human being,
25 namely, the up and the front.

5
Distribution of Feet and Cosmic Alignment

All the animals that, like human beings and birds, have their up separated from their front are two-footed (two of the four points are wings in one, hands and arms in the other). But those that have their front and their up in the same place are four-footed,
30 many-footed, or footless. I call "foot" a part [of the body], connected with a point on the ground, capable of causing movement with respect to place, and, indeed, the feet (*podes*) appear to have gotten even their name from the ground (*pedon*).

Some animals have their front and their back [parts] in the same position—for
706ᵇ1 example, the soft-bodied animals and the hard-spiral-shelled animals. These were discussed previously elsewhere.[3]

3. The most likely reference is *PA* 684ᵇ14–16.

Since there are three places in the universe—an upper, an intermediate, and a lower—the two-footed animals have their upper part aligned with the upper part of the universe, the many-footed and footless animals have it aligned with the intermediate part, and the plants with the lower part. The cause of this is that plants are stationary, toward the nourishment is the up, and their nourishment is taken from the earth. The four-footed animals [have their upper part] aligned with the intermediate region, as do the many-footed and footless animals, because they are not upright. But the two-footed animals have theirs aligned with the upper part [of the universe] because they are upright. This is most of all true in the case of the human being; for its two-footedness is most in accord with nature.

And it is reasonable that the starting-points arise from these parts; for the starting-point is estimable, and the up is more estimable than the down, the front more than the back, and the right more than the left. But it is also correct to state the reverse about them, that because the starting-points are in them these parts are more estimable than their opposites.

6
The Centralized Progressive Movement System

From what has been said it is evident that the starting-point of movement is from the right. However, for anything continuous, of which one part is moved while another remains at rest, to be able to move as a whole while one part stands still, it is necessary, insofar as both parts are moved with contrary movements, for there to be some common part in virtue of which these parts are continuous with each other, and for the starting-point of movement of each of the two parts to be located there, and likewise the starting-point of rest, [and since] with respect to whichever of the oppositions mentioned,[4] a special movement belongs to each of the contrary parts, it is clear that there exists a common starting-point at the natural juncture of the parts in question. I mean of the ones on the right and the left, the ones up and down, and the ones front and back.

The division of the front and back is not of the sort that applies to what moves itself, because there is no animal for which backward movement is natural, nor does the moving animal have any distinction in virtue of which it can make a change in each of these directions; but there is one in accord with the right and left, the up and down. That is why all animals that proceed by using instrumental parts have **707^{a}1** them distinguished not by the difference of the front and back but by the remaining two pairs. By both pairs, but first by the one that distinguishes with respect to the right and left, because it is necessary for this one to be present as soon as there is a

4. I.e., the three pairs of dimensions introduced at 704^{a}19–22.

distinguishing into two, while the other one[5] first appears when there is a distinguishing into four.

Since, then, the up and the down and the right and the left are connected with one another by the same common starting-point (I mean the starting-point that controls their movement), it follows that in everything that is going, properly, to make a movement in each part, the cause of all the said movements must be arranged in a certain definite position with reference to the distances from the aforesaid starting-points (both those arranged co-ordinately in pairs as well as those arranged in a series). This is the common starting-point from which the movements of the right and left, and similarly of the up and down, arise in the animal, and each animal has a starting-point of this sort at a place that is related in much the same way to each one of the starting-points in the parts described.

7
Points of Movement

It is evident, then, that movement with respect to place belongs either only or above all to those animals that make their change with respect to place either by means of two or four points. So, since this pretty much happens above all in the case of the blooded animals, it is evident that none of the blooded animals can move by means of more than four points, and if an animal is moving naturally by means of only four points, this animal is necessarily blooded.

What occurs in animals is also in accord with what was just said. For none of the blooded animals that is divided into a plurality of parts can continue to live for any length of time worth mentioning; nor can it partake of the movement with respect to place in accord with which it was moving while it was continuous and non-divided. But a few of the bloodless and many-footed animals, when they are divided, can continue to live for quite a while in each of their [severed] parts, and they can indeed move with precisely the same movement with which they were moving before they were divided—for example, the so-called centipedes, and other insects with an elongated body; for in all these animals even the back part makes its progression in
707b1 the same direction as the front part. And the cause of their continuing to live when they are divided is that each of them is constituted as if it were something continuous, composed of many animals together.

Why it is this way is evident from what was stated previously.[6] For the animals that are constituted most in accord with nature move naturally by means of two or four points, and likewise also those blooded animals that are footless. For they too move by means of four points through which they make their movement. For they move

5. I.e., the up and the down.
6. 707a6–16.

forward by using two bends; for the right and left are found in the front as well as in the back on the wide side of each of their bends: the front right and the front left in the part that is near the head, the back points in the part that is toward the tail. They seem, though, to be moving by means of two points by touching [the ground] in the front and the back. The cause is that their body is narrow in breadth, since in these animals too the right part leads the movement, and it is balanced by the movement of the back, as in the four-footed animals.

The cause of their bends is their length; for just as tall people walk with their body curved, and their right shoulder leading forward (for their left hip is inclined rather toward the back and their middle part becomes hollow and curved), so one should understand that the snakes too move on the ground with their body curved. Here is a sign that the snakes move just like the four-footed animals; for they alternate the concave and the convex in a part; for when the left of their front parts is leading again, the concave comes to be from the contrary bend; for the right becomes inner again. Let the front point on the right [Fig. 1] be A, and that on the left B, and the back point on the right C, and that on the left D.

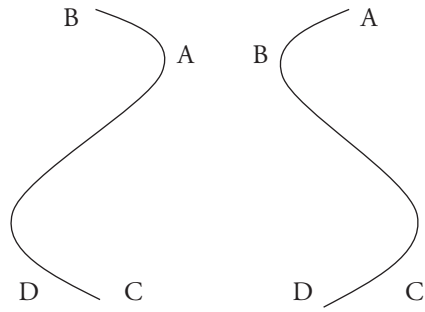

Fig. 1

It is in this way that, among terrestrial animals, the snakes move, and, among aquatic animals, the eels, the conger eels, the torpedo fish, and all the other more snake-shaped animals. Except that some of these aquatic animals have no fins, like the muraenas; still, they use the sea in the way the snakes use both the land and the sea (for the snakes swim in the same manner as when they move on land). Other aquatic animals have only two fins, like the conger eels, the eels, and a certain mullet kind that lives in the lake in Siphae. Because of this, those that are accustomed to living on land—like the eel kind—move with fewer bends in water than on land. The mullets that have only two fins equalize the four points in water by means of their bending.

8
Number of Feet

The cause of footlessness in the snakes is that nature does nothing pointlessly, but rather does everything with a view to achieving what is best from among the available possibilities for each animal, preserving the special substance and essence of each. Further, what we said previously[7] is relevant: none of the blooded animals can move by means of more than four points. From these considerations, it is evident that none of the blooded animals whose length is out of proportion to the rest of their bodily constitution, like the snakes, can possibly have feet. For they cannot have more than four points of movement (for then they would be bloodless); but if they had two or four feet, they would be almost completely incapable of movement, so slow and useless would their movement necessarily be.

Every footed animal has of necessity an even number of feet. For all the animals that make their change with respect to place by using only jumping have no need of feet for this sort of movement, at any rate. For those that use jumping, but for whom this sort of movement is not sufficient, but instead need progression in addition, it is clear that for some of them it is better this way,[8] while for others progression would be impossible otherwise.[9] Since a change of this sort is made part by part, and not by the whole body all at once as in jumping, it is necessary, in turn, for some of the feet to remain at rest and for others to move, and for the animal to move and to rest by means of feet standing in opposition, shifting its weight from the feet that move to those that stay at rest. This is also why no animal can walk by using either three feet
708b1 or only one. For with only one the animal would have no point of support at all on which it could rest the weight of the body, while with three it could rest only in one of two opposite pairs, so that it would necessarily fall while trying to move in this way.

But in animals that are many-footed, like the centipedes, it is possible for progression to come about also on an odd number of feet, as they in fact appear to do if one incapacitates one of their feet, because they can remedy the incapacitation in one row of feet with the remaining number of feet present on each of their two sides. For what happens to these animals is, as it were, a dragging along of the incapacitated part by the other feet rather than proper walking. It is nonetheless clear that these animals too would make their change in a better way with an even number of feet, that is, with no foot missing, but rather with all of them in their opposite rows. For in this way they could restore [the even distribution of] their weight, and they would not sway more to one side than the other if they had all their opposite points of support and not one of the opposite places empty. And

7. 707a19–23.
8. I.e., with an even number of feet.
9. Omitting διότι . . . πόδας.

an animal, when progressing, advances from each one of the two sides alternately; for it is in this way that the return to the initial configuration is secured.

That all animals have an even number of feet, and due to what cause, has now been stated.

9
Bending

That if nothing were at rest, there would be no bending or straightening is evident from the following considerations. For bending is the change from what is straight to what is curved or angled, while straightening is the change from either of these to what is straight. In all the changes mentioned, it is necessary for the bending or straightening to come to be in relation to one point.

Moreover, without bending there could be neither walking nor swimming nor flying. For footed animals stand and take their weight alternately on one or the other of their opposite legs, and as one leg strides forward the other must necessarily make a bend; for the opposite legs are by nature of equal length, and the one that is under the weight must be straight, at right angles, as it were, to the ground. When the other leg strides forward, it becomes the hypotenuse of a right-angled triangle, its square equal to the square on the other side together with the square on the base. But since the **709^{a}1** legs are equal, the one at rest must bend, either at the knee or at the joint (if there is any knee-less animal that walks). Here is a sign that this is the case; for if one were to walk on the ground along a wall, having attached to one's head a reed dipped in ink, the line described [by the reed] would not be straight but zigzag, because it would go lower when one bends and higher when one stands and raises oneself.[10]

It is nonetheless possible to move even if the leg has no bend, as when children crawl. (This was the old account of the movement of elephants, but it is not true.[11]) Movements of this sort also involve bending, either in the shoulders or in the hips. But nothing could walk upright in this way continuously and safely, but would only move like men in the wrestling schools advancing through the dust on their knees, for the upper portion of the body is big, so the legs must be long; but if this is so, there must be bending. For since the standing position is perpendicular [to the ground], if the leg moving forward cannot bend, one will either fall, as the right angle becomes less than ninety degrees, or else one will not advance at all. For if one leg is at right angles and the other is advanced, the latter will be greater, though it is equal; it will have the capacity to be equal to both the supporting leg and the hypotenuse of the right-angled triangle. It is necessary, therefore, for what advances to bend, and while bending one leg, extend the other, incline forward at the same time, make a

stride, and remain above the perpendicular; for the legs form an isosceles triangle and the head becomes lower when it is perpendicular to the base of the triangle.

Some of the footless animals advance by undulations (this happens in two ways; for some do their bending on the ground, like the snakes, while others do so upward, like caterpillars), and undulation is bending; others move by oozing, like the so-called earthworms and leeches. These animals advance with one part leading the way, then draw the remainder of the body to it, and they change from place to place in this manner. It is evident that if the two lines they make were not greater than the subtending one, the undulating animals would not be able to move; for when the bend is extended, it would have made no advance if it subtended an equal line; but in fact the line is longer when the bend is extended, and when this stands still, the animals draw up the rest.

In all the changes mentioned, what moves advances by first extending itself straight and then by curving itself; it straightens itself with its leading part and curves itself with the parts that follow. All the jumping animals too make the bend in the lower part of their body, and in this way jump. And those that fly and those that swim fly or swim, in the one case, by straightening and then bending their wings, in the other case their fins. Among the latter, some have four fins and others, those with a rather elongated shape, have only two (for instance, the eel kind). They swim by substituting a bending of the rest of their body for the missing pair of fins to complete their movement, as was said previously.[12] Broad fish use, on the one hand, the broad part of their body in place of [the second pair of] fins and, on the other, two fins. Fish that are altogether broad, like the ray, do their swimming with the actual fins and with the outer periphery of their body, by bending and straightening.

10
Winged Animals

Someone might raise a puzzle, though, as to how birds move by means of four points, either when flying or when walking, on the supposition that it was said that all blooded animals move by means of four points. However, that is not what was said, but rather that they move by *not more* than four points.[13] Nonetheless, birds could not fly if their legs were removed, nor could they walk without their wings, since not even a human being could walk without moving its shoulders a little. But, at any rate, all do make their change by means of bending and straightening, as was said;[14] for they all proceed upon what underlies them as if the latter

13. 707a20–21.
14. 708b26–27.

were giving way on them, up to a point.[15] So even if bending does not occur in another part, it is nonetheless necessary for it to occur, at any rate, from where the starting-point is—of the wing-like membranes in whole-winged animals, of the feathered wing in birds, and of the analogous part in other animals, such as the fishes. And for some animals, like snakes, the starting-point of the bending is in the joints of their body. **710^a1**

The tail in winged animals is for staying on course in flight, like the rudders in ships. And it is necessary for the tail too to bend where it grows together with the body. That is why whole-winged animals, and some of the split-winged animals whose tails are not naturally suited for the use just mentioned, such as peacocks and the domestic fowl, and in general those birds that are not good flyers, cannot move in a straight course. None of the whole-winged animals has unconditionally speaking a tail; as a result, they are carried along like a rudderless ship, and each of them bumps against anything they chance upon, as do both the ones with a wing case[16] (like dung beetles and cockchafers) and the ones without a wing case (like bees and wasps). And in birds that are not good flyers the tail is useless—for example, the *porphuriôn*,[17] the herons, and all the birds that are able to swim. In place of the tail, they fly by stretching out their feet, and use their legs in place of their tail for staying on course in flight.

The flight of the whole-winged animals is slow and weak because the nature of their wings is not in proportion to the weight of their body, but instead the weight is great while the wings are small and weak. Just as if a cargo ship, then, were to try to use oars to navigate, so in this way do these animals use flight. The weakness of the wings themselves and also of their outgrowth contribute to some extent to what has been described. Among birds, the peacock's tail is sometimes useless[18] because of its size, and sometimes of no benefit because of the shedding.

But birds are in a condition contrary to the whole-winged animals with respect to the nature of their wings, and above all the swiftest flyers among them. The crook-taloned birds are of this sort; for, in them, swiftness of flight is useful for their mode of life. And the remaining parts of their body seem to conform to their specific movement. In all of them, the head is small, the neck not thick, and they have a strong, sharp breast—sharp so as to be forceful, as if it were the prow of a fast-sailing ship, and it is strong due to the nature of its flesh, in order to be capable of pushing away the air hitting against it; and it does this easily and without effort. The back parts are light and come together again to a narrow point, in order that they may follow the front parts without dragging the air because of their breadth. **710^b1**

18. I.e., for flying.

11
Two-Footedness

As regards these matters, let it be determined this way. But why it is necessary for an animal that is to walk upright to be two-footed, and for it to have the upper parts of its body lighter, and those that lie under them heavier, is evident. For only if arranged in this way would the animal be able to carry itself easily. This is why a human being, being the only upright animal, has the biggest and strongest legs among footed animals in proportion to the upper parts of its body. What happens in the case of little children also makes this evident; for they are unable to walk upright because they are all dwarf-like[19] and have the upper parts of their body bigger and stronger in proportion to their lower parts. But as they grow older, their lower parts receive more growth until they acquire the appropriate size, and at that point children make, by means of their bodies, their walking upright.

Birds, since they are light, are two-footed because their weight is located at the back, just as people make bronze horses with their front legs raised up. But above all the cause of their being able to stand, although they are two-footed, is that they have a haunch[20] like a thigh, and of such a size that they seem to have two thighs, one in the leg before the joint, and another going toward this part from the rump; it is not a thigh, though, but rather a haunch. For if it were not of such a size, there would be no two-footed bird. For, just as in the human beings and in the four-footed animals, the thigh and the rest of the leg would then begin right from the haunch, the latter being short; with the result that the whole body of birds would be inclined forward too much. But as things stand, being long, the haunch stretches up all the way to beneath the middle of the abdomen, so that from there the legs, having been put underneath as a support, carry the entire body.

It is also evident from these considerations that it is not possible for the bird to be upright in the way that the human being is. For the nature of wings, as birds have their body in fact arranged, is useful to them; but it would be useless if they were upright, like the winged cupids that people paint. At the same time, it is also clear from what has been said that neither a human being nor anything else with this sort of shape can be winged, not only because it will then move by means of more than four points, despite being blooded, but also because having wings would be useless to them when they move in accord with nature. And nature does nothing contrary to nature.

12
Leg Bending in Human Beings and Four-Footed Live-Bearing Animals

It was stated previously[21] that if there were no bending in the legs or in the shoulders and hips, none of the blooded footed animals could advance; that there would be no bending if nothing were at rest;[22] that human beings and birds, although both are two-footed, bend their legs in contrary directions;[23] and further that the four-footed animals bend their legs in contrary directions both with respect to themselves and with respect to the human beings.[24] For human beings bend their arms toward the concave and their legs toward the convex, while the four-footed animals bend their front legs toward the convex and their back legs toward the concave; and birds do likewise. The cause of this is that nature crafts nothing pointlessly, as was said previously,[25] but everything with a view to the best from among the available possibilities.

So, since in all the animals that in accord with nature change with respect to place by means of legs, when each leg is standing, the weight is on it, but when the animals move forward, the leading foot must be light by virtue of its position, and the progression continuing without interruption, the weight must fall on this foot again, it is clearly necessary for the leg, after being bent, to become straight again, with the point of the foot that has been thrust forward and the shin at rest. And it is possible for this to happen and, at the same time, for the animal to advance, if the leading leg has a forward bend; but it is impossible if the leading leg has a backward bend. For in the former way the extension of the leg will take place while the body is moving forward, but in the latter way while the body is moving backward. Further, if the bend were backward, the positioning of the foot would take place through two movements that are contrary to each other: one backward and the other forward. For it is necessary, **711b1** in the bending together of the leg, for the last part of the thigh to advance backward and for the shin to move the foot forward from the point of bending. By contrast, if the bend is forward, the progression mentioned will take place not by contrary movements but by a single forward movement.

The human being, then, because it is two-footed and in accord with nature makes its change with respect to place by means of legs, bends its legs forward due to the cause mentioned, and its arms toward the concave, as is reasonable; for the arms would be useless, were they bent in the contrary direction, for the employment of the hands and also for taking food.

The four-footed live-bearing animals must bend their front legs toward the circumference, since they lead the progression and are situated in the front part of
